

A Report on the Work done by the Research Staff under the Locust Research Entomologist to the Imperial Council of Agricultural Research at Karachi during the year 1936

A Report on the work done by the Research Staff under the Locust Research Entomologist to the Imperial Council of Agricultural Research at Karachi during the year 1936.

BY

Rao Bahadur Y. Ramchandra Rao, M.A., F.R.E.S., Locust Research Entomologist, Karachi.

An account of the progress made during the current year is submitted in the present report, which is being presented in four different parts. Part I will deal with the General Report on the results of survey work and ecological studies. The results of the experimental work carried out at Pasni, Ambagh and in parts of the Desert areas will be dealt with in Part II, while studies of locust movements in the past as correlated with meteorological data, as well as various miscellaneous items, and the present year's conclusions will be included in Part III. Part IV will be devoted to suggestions for future work.

PART I.

GENERAL REPORT.

I.—Personnel.

I was in charge of the Locust Research Scheme with headquarters at Karachi throughout the year.

Staff at Karachi.—Dr. S. Mukherji, D.S. (Cal.), was appointed as Assistant Entomologist at headquarters from the 10th January 1936, and attended to the experimental work and collections at Karachi and was in charge of the office during my absence from headquarters. Mr. Rashid Ahmad, B.Sc. (Hons.), worked as Biometrical Assistant at Karachi till the 16th May, when he was pested to Pasni to officiate as Mokran Survey Assistant. Mr. Ram Lal Gupta, M.Sc., was appointed as Biometrical Assistant from the 10th October. Mr. Chandar Parkash, B.Com., Senior Compiling Assistant, left the Locust Scheme on the 3rd October to take up an appointment in the Imperial Institute of Sugar Technology, Cawnpore, and his place was filled up by Mr. V. Ramani. Mr. H. G. Sheikh, Second Compiling Assistant, was promoted as Accountant in the place of Mr. R.-L. Mehta transferred to Cawnpore in October and Mr. A. Lateef Sabir was appointed in the vacancy.

Staff in Southern Baluchistan.—Dr. M. L. Roonwal, M.Sc., Ph.D. (Cantab.), continued to work as Assistant Locust Research Entomologist at the Pasni Locust Research Station in charge of the work in the Mekran area, and Mr. S. M. Taqi Ahsan, M.Sc., as Locust Research Assistant at Pasni. Mr. Rahmatullah Butt, M.Sc., was appointed as Mekran Survey Assistant with headquarters at Pasni at the end of December 1935 and attended to the supervision of locust survey work in Mekran till the 7th May 1936, when he left M253ICAR

Pasni on leave and could not return for reasons of ill-health. Mr. Rashid Ahmad, Biometrical Assistant, officiated in his place and was ultimately confirmed as Survey Assistant at Pasni. Mr. R. N. Batra, M.Sc., continued to be in charge of the Ambagh Field Research Station. A new outpost in charge of a Fieldman was opened in July at Panjgur in Mekran for locust survey work.

Staff in the Sind-Rajputana Area.—Mr. Des Raj Bhatia, M.Sc., was stationed at Barmer in charge of the three Locust Outposts at Chachro, Nokh and Sardarshahr and of the locust survey work in the Desert area. The Outpost at Mahwar near Barmer was abolished from April 1st, 1936, as recommended by the Locust Committee.

II.—ITEMS OF LOCUST RESEARCH WORK IN PROGRESS DURING THE YEAR.

- Ecological Study of the Solitary Phase Locust in its natural Habitats.—
 Work was carried out in the following centres:—
 - A. Pasni: representing the winter-rain areas of the Mekran coast.
 - B. Ambagh: as typical of the summer-rain areas of that coast.
 - C. Chachro: representing the southern areas of the Indian Desert, viz,
 Thar-Parkar and Mallani.
 - D. Nohh: as a centre for the northern area of the Desert,
 - E. Sardarshahr: for the north-eastern or Bikaner areas.
 - 2. Distributional Survey of the Habitats of the Locust .-
 - A. Mekran Circle.—Surveys on the Coastal reks, and in the hinterland of Mekran, including Kech, Kolwa, Kulanch, Dasht and Panjgur, with Pasni, Gwadar, Turbat and Panjgur as centres.
 - B. Lasbela Circle.—Surveys on the Coastal reks and in the hinterland of Lasbela, with Ambagh as centre.
 - C. Bikaner Circle.—Surveys in the Bikaner desert areas with Sprdar-shahr as centre.
 - D. Jaisalmer Circle.—Surveys in the northern and eastern parts of the Jaisalmer area and in parts of north Marwar, with Nokh as centre.
 - E. Thar-Mallani Circle.—Surveys in the desert areas of Thar-Parkar District of Sind, and of south Marwar, with Chachro as centre.
 - F. Khairpur Circle.—(For part of the year) for surveys in the Khairpur-Bahawalpore areas during the summer months.
- 3. Study of the Movements of Locusts—either as swarms or individuals during the year.
 - 4. Study of Old Records.—Compilation and mapping of Locust Data.
- 5. Study and Correlation of Meteorological Data in connection with recorded locust data.
 - 6. Study of the Fauna and Flora collected during Survey Work.
 - 7. Biometrical Study of the Locust Collections.

III.—SURVEY WORK.

Tours.--In carrying out locust survey work, the plan adopted in 1935 was in general followed, intensive surveys around the various centres as well as long distance surveys on a 50-100 miles' radius around them being carried out throughout the year. In addition, certain special visits were also arranged, such as tours in the West Sind, Kachhi and Dera Ghazikhan areas, surveys in the Khairpur-Bahawalpore areas by a Fieldman stationed at Khairpur during June-October, and tours across the desert from Khairpur into Jaisalmer and Marwar, and from Jaisalmer into Bahawalpore. In the Mekran area, owing to the enormous stretches of area to be covered by the Turbat Fieldman. it was found impossible to arrange to have a fairly frequent inspection of the hinterland of Mckran in order that the development of 'outbreak centres' in that area might be detected in time. With the sanction of the Imperial Council of Agricultural Research, a new Outpost was opened at Panjgur in charge of a Fieldman in July, who was instructed to make fairly frequent surveys of the Gar-Sehgazan, Dasht-Shahbaz and Kolwa areas, while the Turbat Fieldman was to restrict himself to the Kech, Buleda and Parom areas.

As instructed by the Locust Committee, a standard form of reports to be submitted by Fieldmen engaged in Locust Survey work was drawn up and submitted for approval.

In computing the density of locust populations, the rough formula worked out last year was followed. It was felt, however, in the course of the work that there was no necessity to have a different rate of computation for surveys undertaken in winter as compared with those of summer, since survey work was attended to at the hottest part of the day in winter, when locusts were fairly active. Again, experience this year at Pasni has shown that surveys on camel-back have on most occasions given very unreliable results, as compared with foot-surveys made in parts of the area examined. Surveys on camelback would appear to be useful only when the locust population is fairly dense and the locusts happen to be active and excitable, as they were during the period of the Locust incursion of July-August 1935.

Statements A-I, A-II, and A-III contain particulars of all tours actually carried out in the Sind-Rajputana, Mekran and Lasbela Circles, each tour being given a serial number for purposes of reference.

Results of Locust Surveys.—The results obtained in regard to locust finding this year have been classified under:—

I. Results of extensive surveys.—Which have been given in Statements B-I, B-II and B-III for Sind-Rajputana, Mekran and Lasbela Circles respectively, and II. Results of intensive surveys.—Shown in Statements C-I for Pasni, C-II for Gwadar, C-III for Ambagh, C-IV for Chachro, C-V for Nokh and C-VI for Sardarshahr. As in 1935, the results have been arranged according to the different seasons, and, as far as possible, the approximate population density has also been indicated.

Weather in the regions of habitat of the Descrit Locust in N. W. India in 1936.

A review of the seasonal rainfall in 1936 is briefly made below, as it is essential for interpreting the locust developments of the year.

Winter Rainfall.—The first western disturbance of 1935-36 winter season made its appearance on the 8th October 1935 in the winter-rainfall areas of Baluchistan, Iran and N. W. India, and the last one during the last week of May 1936. Altogether about 57 different western disturbances were recorded during the season of 1935-36.

During December, there was very little minfall anywhere except in the Bushire area, which recorded a total of 8 inches. In January, there was fairly good rainfall during the earlier half of the month, the principal falls being Muscat 5.60", Sharjah 2.10", Bushire 3", Gwadar 0.50". Pasni 2", Ormara 1.80", Jask 1.90", Bahrein 0.60" and Quetta 1.70". The latter half of January and the first fortnight of February proved to be a dry period. During the last ten days of February, a fall of 2.50" was recorded at Ormara and 0.80" at Pasni, owing to the development of two depressions along the coast. During the early half of March, Gwadar received a fall of 2.50", Pasni 0.90", Ormara 0.90" and Turbat 1.15". There was little rainfall subsequent to this period anywhere except at Panjgur (0.53" on the 19th May), Kalat and Quetta about middle of May.

In the Indian Desert area, the influence of the western disturbances was but little felt during 1936, except in February when a few good fells occurred in the Jaisalmer-Bikaner area.

The winter rainfall in the Mekran coastal area amounted in all to about 4 to 5 inches during the year, which is much below the normal (about 7 inches at Pasni).

Summer Rainfall .- The South-West Monsoon set in very early this year both in the Arabian Sea and the Bay areas by about the 19th May, causing rainfall on the West Coast and the formation of a cyclone at the head of the Bay. This was followed by another depression which appeared early in June, in the Bay of Bengal, and though both brought very heavy rainfall into the castern parts of India, they did not extend their influence into N. W. India, except in parts of east Rajputana. Widespread thunder shower rain occurred between the 20th and 26th June in Rajputana. Punjab and South Sind, e.g.. Bikaner and Jodhpur 2 inches each. A depression which appeared in the last week of June, however, passed across the Rajputana desert area and caused general rainfall at the end of June and during the first week of July, Badin recording about 10", Karachi 3", Bikaner about 4", Jodhpur about 4", Barmer 2", Khanpur 1½", Bahawalpur 2", Multan 1½", Chachro 3-80", Mithi 3" and Bela 1". The influence of this depression extended also into Lasbela and Mekran. Towards the middle of July, there was some rainfall in Bahawalpore and Upper Sind, but on the whole the latter part of July was dry, and the drought that set in continued upto the 10th August in the Rajputana area. A depression that passed over north Rajputana between the 12th and the 16th gave very heavy minfall in parts of Bikaner and Jaisalmer, Nokh recording 16", Bikaner 10", Srikolayatji 15", Surpura 13", Ratangarh 8" and Mahajan 4", but in other parts of the desert the rainfall was light. Between the 19th and

the 23rd August, there was widespread rainfall in west Rajputana areas, Barmer recording 1½", Jodhpur 1½" and Bikaner 2". During the early half of September, fairly widespread rainfall occurred between the 8th and the 13th in south Rajputana, Southwest Punjab, south Sind and eastern Baluchistan, under the influence of a depression moving north-westwards over the Central Provinces. Multan recorded 4", Bahawalpore 1½", Khanpur 1", Badin 3", Chhor 2", Chachro 1.25", Barmer and Jodhpur 1½". Widespread thunderstorms occurred on the 16th and the 17th September in Baluchistan, Lasbela 2", Sibi ½", Kalat ½", etc. The monsoon began to withdraw from the country about the 19th September, and thereafter the weather continued to be dry till the end of October.

With the withdrawal of the monsoon, there was a rapid fall of atmospheric humidity in the Rajputana area, accompanied by a sharp rise in temperature, maxima upto 105°F, being recorded, leading to the development of a zone of high saturation deficiency. Easterly and north-easterly winds generally prevailed in October and November.

Under the influence of a cyclonic storm which developed in the south-castern part of the Arabian Sea and travelled north towards the Kathiawar coast between the 13th and the 16th November, some rainfall occurred in parts of Sind and Rajputana. Badin 0.60°, Chhor 1°, Jodhpur 0.70° and Bikaner 0.50°.

Western disturbances began to appear in the last week of October, but were generally feeble. In the latter half of November, however, rainfall was recorded, in several places in the Persian Gulf area: Bushire 3", Jask 14", Bahrein 1", Charbar 4" and Muscat 4".

Results of Locust Survey Work in 1936.

- 1. Distribution of locusts during the winter and spring seasons.—In the western 'rek' areas of the Melran Coast, viz., Ormara, Pasni and Gwadar, and in Kulaneh and Dasht. locusts were present in fairly good numbers during December 1935 and January 1936, and the population was composed partly of the remnants of the July migrants of 1935 and partly of the November migrants of the new generation from the Rajputana areas. In the summer rain areas of Lasbela and Sind-Rajputana desert, there were few locusts to be seen in the Sardarshahr and Nokh areas, but around Chachro and Ambagh and in the Mohangarh-Basanpir region of the Jaisalmer area, there were fair numbers of locusts to be found during December, January and February, whereas during the previous year these areas were more or less clear of locusts. By April and May, however, most of the locusts had disappeared in these places, presumably by migration elsewhere.
- 2. Breeding in the Winter Rainfall areas.—The first heavy shower (1.32") was received at Pasni on the 9th January and the first egglaying probably occurred towards the end of January. The first hoppers (including I and II instar ones) were detected by the survey staff on 21st March, and the first adult of the new generation was noted on the 18th April. It is likely, therefore, that the earliest hoppers had emerged by the end of February or at the

beginning of March. As the rainfall was below normal, breeding was rather scanty and was more or less confined to the special areas. The last hopper was seen on the 18th May whereas during the year previous, hoppers were noticeable on the special areas even upto the first fortnight of November. The contrast between these two years in this matter is obviously to be attributed to the difference in the amount of the rainfall and the consequent difference in the moisture-content of the soil and the sub-soil.

Egglaying occurred almost at the same time at Gwadar, Pishukan, Jiwani and Ormara, and the first adult of the new generation was noted on the 11th April at Jiwani and on the 19th in the Ormara area. In Kulanch, a fair number of hoppers was noticed in various places, viz., Kandasole, Sardasht, Ban, and Nokbur during March and April and part of May. In the Dasht area, hoppers were found only in the neighbourhood of Suntsar.

In Kolwa, fairly good numbers of locusts were noticed by the Turbat Fieldman during the third week of March all over the valley between Hoshab and Awaran, but unfortunately this area was not visited again till the middle of June. It was found subsequently by enquiries made of the local inhabitants that hoppers of the gregaria type had appeared on a young juari crop at Rodkan in Kolwa by the end of March and had attacked the crop. It was reported that after rainfall at the end of February, a fair number of browncoloured locusts (about 100) were found flying about and pairing in a field and these had presumably laid eggs, from which large numbers of blackcoloured hoppers hatched out. The hoppers are reported to have turned green at a later stage, and to have transformed by the end of April into pinkish adults, which flew away within a week of acquiring wings. Obviously this is an interesting instance, wherein an 'out-break' centre had developed by the concentration of migrants of the old over-wintered generation, derived from the coastal reks. The migration may be presumed to have been caused by want of sufficient rainfall along the coast and to have been helped by the strong westerly wind accompanying the passage of western disturbances.

Another place where hoppers were noticed in the interior of Mekran this year was at Nigor Kan Daf near Thana Daragh in the Panjgur area, where 65 hoppers of green colour were found on "Kapochum" (Chrosophora sp.) bushes in the midst of a Juari field on the 25th June. They were of I, II and III stages. They condently represented the second generation of the season, the eggs having been laid in the latter half of May. presumably after the thunder-shower rain recorded on the 19th May at Panjgur. The Survey Assistant, who visited this place about a fortnight later, found about 16 hoppers of the III and IV stages. There is little doubt that, in a year of heavier rainfall and consequent greater multiplication of the locust, this place would have functioned as one of the "outbreak" centres.

Hoppers were not observed anywhere in Mekran after May with the exception of the instance mentioned above. Since, however, the Fieldman during his visit in August collected a specimen with hyaline wings between Rodkan and Hoshab on the 9th August, and since some rainfall is known to have occurred in parts of Kolwa in the middle of June, it is presumed that some slight breeding had taken place in Kolwa during summer. The collection of one or

two clear-winged specimens evidently of recent origin in August in the Ormara and Gwadar areas, would also possibly indicate that some breeding had taken place in the valleys of the hinterland.

In April-May, an attempt was made to study the history of the hopper population in a part of the "rek" area at l'asni. A plot measuring about 500 sq. yards in the Gandbako area containing flourishing 'Marrand' bushes which was naturally that off on all sides by walls of moving dunes, was intensively examined periodically, the hoppers being re-released, after noting the actual population. On the 23rd April. 13 hoppers of I, II and III stages were noted, on the 28th, only 5 green hoppers of I, II and IV instars were to be seen, on the 8th only two III stage happers and on the 14th, none were to be found. Since the decline in population could not be ascribed to a scattering or a migration of the hoppers, it is surmised by the Assistant Entomologist that it must have been due to the activities of natural enemics, especially lizards, centeipedes, ants and spiders.

3. Distribution of locusts in May and June - During May, a gradual diminution of population was noticeable on the Pasni reks, in spite of the anpearance of the new generation of adults after the occurrence of local breeding. On the other hand, at Ambagh the locust population was gradually on the increase during May. At Chachro, it was noted that, while only one locust was seen during the first fortnight of May, as many as nine specimens (denoting a population rate of 80 to 320 per sq. mile) were noted during the latter half of the month. During June, the population had considerably increased both at Ambagh and Chachro, while at Nokh fair numbers of locusts were noticeable during June, the first specimen being seen on the 31st May after an interval of complete absence of over two months. At Sardarshahr, the first specimen was found on the 21st June. At Pasni, a sudden increase in the population was noticed from the 28th May onwards, the density rate rising from about 70 to 100 per sq. mile to 300 to 700 per sq. mile. The specimens noticeable were moreover characterised generally by the presence of a more or less pronounced patch of light pink, blue or mauve colour at the base, and the presence in many of the larvee of red mites on the wings, sudden rise in population was noticed also at Ambugh from the 27th May onwards, the specimens similarly carrying red mites and bearing the colour patch at their wing-bases. A rise in population was noticed at Chachro from the 9th June, and at Nokh from the 11th June. At Gwadar an increase in the numbers observed was noticeable about the 26th May, while in the Ormar area the Survey Assistant noted a fairly dense population in some localities during the middle of June varying from 200 to 1,000 per sq. mile, and the specimens are said to have carried red mites and to have possessed blue or mauve bases. He also reports that the Naih of Ormera had informed him that a sudden increase of locusts had been noticed on the 2nd June in the neighbourhood of Ormara. All the above data appear to indicate that an incursion of locusts had taken place over a wide area, similar to that of July 1935, but of very much lower magnitude and intensity. A study of the meteorological conditions of the interior areas of Baluchistan as represented by the reporting stations of Nokkundi, Dalbandin and Panjgur showed that, while the general temperature and humidity conditions of these areas were fairly moderate upto the end of April, an accentuation of the conditions was noticeable during the second week of May, the temperature maxima reaching 109° to 115°F., and the Relative Humidity percentages generally ranging from 25 to 50 at 8 A.M. in the mornings, and these conditions were maintained till the 23rd June, when conditions were somewhat changed by a temporary extension of the influence of the monsoon in this area. It is presumed that locusts reaching this area in May-June from the coastal rek areas of British and Iranian Baluchistan were deflected south-castwards, and caused to migrate into the coastal reks of Mekran and Lasbela and subsequently, therefrom, into the Indian areas, entry into which would be facilitated by the strong south-west winds. A biometrical examination of the forms found in May-June showed a preponderance of intermediate ratios and of six-striped forms

4. Breeding in Summer Rainfall Areas.—During the spring months, one second-stage hopper was noted on 'Kullichk' (Cyperus) at Khandewari in the west Lasbela area during April, and indicates that slight breeding had occurred in this area in spring. One IV-stage hopper was found on 'Booh' (Aerua javanica) between Tarana and Mohangarh in the Jaisalmer area on the 24th April, and this indicates that some slight breeding had taken place in this area also, under the influence of about ½ inch rain received in the Mohangarh area in February. In the Dera Ghazi Khan area, good numbers of green hoppers were met with in April and May on Aerua javanica. In the same area hoppers were found also in summer, during September, feeding on Aerua, Tribulus and Indigofera (Bekkar).

During June, locusts with blue or mauve wing-bases, presumed to be migrants from the western breeding areas, were found distributed all over the desert areas in small numbers. After the fall of rain by the last week of June the mauve tinge was lost and the wings assumed a bright yellow colour, indicative of maturity.

Egg-laying occurred wherever there had been good rainfall. In considering the extent and the intensity of the breeding that occurred this year in the Sind-Rajputana area, the best method would be to follow the order of the rainfall.

Though the monsoon commenced early this year, the first showers received were in the shape of thunder-storm rain between the 20th and the 26th June. At the end of June, a depression which travelled across the desert gave general rainfall over the whole area between the 29th June and the 4th July, but good falls were recorded only in rather restricted areas. In the Bikaner region, the area of rainfall was confined to a long strip 30 to 40 miles broad passing along the line Mahajan-Bikaner-Srikolayat-Jodhpur, both Nokh and Sardarshahr on either side of this strip not having received any considerable rain. Good rain fell all over the Thar-Mallani areas in the south, and also in parts of the Jaisalmer area. The third burst of rain occurred in the middle of August, when very heavy rains were received in the course of a week (10 to 16 inches) in a rather restricted area enclosing Nokh, Girasar, Srikolayatji, Bikaner, Surpura, Sri Dungargarh and Ratangarh. Localities surrounding this area also received fairly good rainfall, though in smaller amounts. There was little rainfall, however, in the southern area at this time.

The fourth round of rainfall occurred in the first fortnight of September, when under the influence of a depression fairly good falls were received in South Marwar and southern Sind.

- (1) First batch of Breeding.—On the 28th and the 30th July some V-instar hoppers were found at Girasar and Srikolayat, which evidently belonged to the earliest batch of egg-laying that had occurred soon after the first showers received about the period—20th to 25th June. Younger hoppers were also found, probably belonging to later batches of eggs laid after the rainfall of 30th June. In the Chachro area, the first hoppers (II-instar) were noticed on the 3rd August, though the first adult of the new generation was found there on the 10th August. At Hayat-jo-Tar in the southern Thar area, an adult of the new breed was noticed as early as the 3rd August, which would indicate that eggs had been laid soon after the first thundershowers received about the 22nd June. In the east Jaisalmer area, the first adult was noted on the 19th August and around Barmer on the 17th. Hoppers of various stages were observable in the Chachro area till the end of August, and since I-instar hoppers were found as late as the 21st August, it is evident that egg-laying had been continuing for 5 to 6 weeks after the last heavy fall of the 1st July.
- (2) The Second batch of Breeding .- The second batch was found associated with the heavy rainfall of August in the Bikaner area. At Nokh and at Sardarshahr Outposts, locusts were not observable during the greater part of July and the first week of August, but with the commencement of rains about the 8th August, they began to be met with in good numbers in these places. In the beginning, the locust population consisted almost entirely of yellowwinged individuals of the old generation, which began to lay eggs immediately. It is surmised that these locusts had been brought in here from some other area by the high winds that accompanied the passage of the depression. During the latter half of August, individuals of the new generation were also met with at Nokh and Sardarshahr, some of which were found to have mature eggs, and indeed showed clear evidences of having laid eggs by the end of August and the beginning of September. It is evident, therefore, that there has been an overlapping of generations among the hoppers noticed in September, part of which were of the first generation, and the rest belonged to the second generation of the season. During September, quite large numbers of hoppers were found in many places, especially in the Bikaner, east Jaisalmer and Bahawalpore desert areas, though gregarious hoppers were not encountered anywhere.
- (3) The Third Batch of Breeding.—With the fall of 1.25" on 10th Sept. at Chachro, oviposition seems to have occurred in the Chachro area, leading to the appearance of I-stage hoppers at the end of September and the beginning of October. Hoppers were being met with at Chachro till the end of October. Similar breeding would appear to have occurred to a small extent in parts of Thar and Mallani. The hoppers in this area definitely represent the second generation of the season.

Similar rainfall would appear to have fallen in parts of Jaisalmer and Bikaner in September and led to an extension of breeding into November.

M253ICAR

Quite large numbers of hoppers were noticeable in the Bikaner-Jaisalmer area throughout October, and there is little doubt that for the most part they represent the second generation of summer breeding.

There was some mainfall in November in many parts of the desert area but it is unlikely that it will lead to any further breeding owing to the setting in of winter conditions.

Breeding in the Lashela Area.—Light rainfull occurred on the 25th June, and again during the first week of July (1-32 in.) This led to light breeding in the neighbourhood of Ambagh in July-August, and the appearance of new generation adults about the middle of August. Somewhat heavier breeding would appear to have occurred in the Got Sherkhan area to the north of Ambagh.

4. Distribution of Locusts in the Autumn.—With the withdrawal of the monsoon by the 19th September, a great change was noticeable in the general meteorological conditions of the Sind-Rajputana area. This was studied by Mr. Bhatia at Chachro during the current year, and the following observations were made:—

		Open Black	Sercen	Serren	Serven		Wind Direction	
Month and d	nte	Pulb 2" above ground Aver. Max. (empers- ture.	Av. Hav. tempera- ture	Av. Min Rel Humidity	Esapora- tion	Rain	Moroing	Affer- noon

These observations indicate that there was a considerable rise in the general temperature maxima, in the solar temperatures affecting the soil surface, and in the general evaporative power of the atmosphere, as well as a considerable drop in the relative humidity of the atmosphere. Conditions were thus obviously adverse for an animal living on the surface of sandy soils like the locust, and it is presumed that these would confluce to cause it to rise high into the air, where the prevailing wind-direction would govern its further movements.

The conditions analysed above were more or less typical of the situation throughout the desert areas at this time of the year, the degree of development of the various factors, of course, varying with local conditions of rainfall and vegetation. At Chachro, the locust population was fairly dense till the 24th, but on the 25th, Mr. Bhatia reports, there was a fairly heavy storm coming into Chachro from the north-east in the evening, and after this date the local locust population almost vanished completely, since only 11 individuals were noted during surveys in the course of the next two months. Similarly at Nokh and Sardarshahr also, the population density was very low during the latter half of September and the early part of October, though hoppers were being met with in good numbers. In these areas, however, the population began to increase during the latter half of October, and during November the density was greater yet, by reason of the appearance of the adults of the second generation. Apparently the atmospheric conditions during November had greatly improved by the general fall of day temperatures, and, though the humidity was low, the urge for migration was apparently not much felt. It would be of interest to watch the further history of these large populations at present to be found in the northern part of the Indian Desert, and to determine whether these would migrate west at the end of the cold season or move north, east or south, in February-March.

At Ambagh, Mr. Batra noted a slight rise in population during the surveys carried out in the latter half of September, and on the 28th and the 30th, the rise was definitely pronounced reaching 500 per sq. mile. The forms were also found to have mauve wing-bases and to carry mites, and were evidently migrants, and when the rise in population at Ambagh is coupled with the reported disappearance of locusts from the Chachro area, after the 25th September, the inference to be made is rather suggestive of the origin of the migrants from the Thar-Mallani area. Surveys at Ambagh showed that the migration was continued throughout October, though at the end of the month there was a specially large rise between the 28th and the 30th. The increase in the number of migrants was maintained throughout November. At the beginning of November two forms with 8 eye-stripes were noted among the migrants, as also one form carrying Tyroglyphid mites on its body. These facts are rather interesting, since the only region where 8-striped forms were found in nature was the west Bikaner area this season, and Tyroglyphid mites were also noted mostly in the Bikaner-Jaisalmer region.

At Pasn, a small incursion was noticed between the 19th and the 26th September, and this is probably to be correlated with certain duststorms that prevailed in the middle of September in Baluchistan, and had been observed and recorded by the Fieldmen then touring in parts of Kolwa and Lashela. The main direction of the storms was from the north-east to south-west, and it is presumed that it was some of the carliest migrants to arrive with these winds that had been recorded at Pasni in the latter half of September. A second small incursion of new generation locusts was detected during surveys in the early part of October, and it is possible that these were part of the contingent recorded by Mr. Batra at the end of September.

Dr. Roonwal reports that at the end of October a fairly defined immigration of clear-winged locusts which had attracted even the notice of people

at Pasni was recorded by the survey staff. As the incursion continued even in November, it is possibly contemporaneous with the October-November incursion at Ambagh.

Similar migrants were noted by the Survey Fieldman during October and November in the Ormara area, and during November in the Gwadar area.

5. Confirmation of the Phenomenor of migration among the Solitaries.— From the statements made above, it is clear that in May and June, there had been a migration from the western winter rain areas into the eastern regions subject to summer rainfall, and in the autumn months. i.e., between September and November, a return migration from the desert areas into the western rek areas.

In deciding whether a locust specimen collected in the field is a migrant or not, reliance has been placed on some of the following characters:—

- Any decided differences in the biometrical and physical characters
 of the specimens from those of the local population of the place
 at the time being, c.g., in the ratios, in the eye-stripe characters,
 in the general colour, etc.
- 2. The occurrence of external parasites. The occurrence of red mites, i.e., the larval stages of Trombidium grandissimum (?), is one of the indications that the specimen had been living for some time past in a region where good rainfall had occurred.
- 3. The colour of the wing: Hyaline colour would indicate a recently developed generation, while deep yellow, a state of sex-maturity. In many migrating specimens patches of pink, blue or mauve are often seen at the base of the wing, which appear to vary in intensity with the length of time they have been on the wing and with the degree of brightness of the sun-light.

In regard to the development of pink or mauve colour at the base of the hind-wing, certain experiments were devised in order to find whether it can be attributed to the effect of the play of the sun's rays during the period of active flight. Statement—I—1 summarises the results of these experiments.

While examining some of the locusts in a cage kept in the sun, during my visit to Pasni in May 1936, I observed that the hind-wing under the malformed elytron of one of the locusts showed a definite tange of pink. This Observation suggested the idea of removing the elytro of some of the locusts to note the effect of exposure to the sun's rays. A cage 3 ft. square by 3 ft. high was therefore, set up at Pasni, in which some recently transformed locusts were introduced after having their right elytra removed, as also certain others, both the elytra of which had been excised. The cage was kept in the open fully exposed to the sun, which was very bright and hot during May and June. The course of a week or two, it was found that in all cases the wings exposed to the sun had acquired a pink colour, which gradually deepened into mauve. By July, with the appearance of cloudy worther, both pink and mauve disappeared completely with the onset of yellow colour indicating maturity. In the case of specimens in which only the right clytra had been removed, the appearance of a tinge of pink or mauve was noted even under the left elytron, though, of course, the colour was by no means as intense.

These experiments were repeated again at Pasni in November-December with fairly conclusive results.

Experiments on similar lines were carried out at Karachi and Ambagh. The first set of experiments, which were set up at the end of June, gave only negative results both at Ambagh and Karachi, as with the advent of monsoonish weather characterised by conditions of high humidity and lack of sun-shine the wings rapidly assumed a bright yellow colour.

In the second and third sets, carried out in September and November respectively, the development of pink or manye colour was definitely noted in the course of 2 to 4 weeks in many of the specimens. At Karachi, the results were not so decisive as at Ambagh, as on account of the existence of high buildings all round the place where the cages were kept, the locusts were not getting sufficient sun-shine except during mid-day.

On the whole, however, these experiments have shown that exposure to sunlight may lead to the definite development of pink or mauve in the wings, so that the existence of pink or mauve at the base of the wings may correctly be taken to be an indication that the locust in question had been undergoing an active migration flight.

The occurrence of External Parasites on locusts.—Locusts have been known to be subject to the attacks of red mites. These are the larve of the Velvet Mite—Trombidium grandissimum, which appears in large numbers on the ground soon after the first heavy fall of the season. After pairing and leading an active life on the surface of the ground for some time, it disappears entirely, presumably by burnowing into the sandy soil. Eggs are probably laid in the soil, and the larval mites on hatching actively search for their hosts, which are mainly locusts and grasshoppers. They attach themselves to the wings and feed on their blood. When fully blooted, they drop off for undergoing their further life-history. The young nates appear about a month after the first heavy fall, and may at ach themselves to any locust, whether of the new or the old generation, that may be present at the time. Locusts of the second generation are generally free from mites. The presence of a locust specimen carrying red mites in an area where there has been no recent fall of rain ought therefore to be taken to be an indication of migration.

A second kind of mite was noted this year on locusts in the Sind-Rajputana area, and this mite, which has been provisionally classified at the British Museum as a Tyroglyphid, has the habit of living in small colonies on the meso-and meta-notal areas, and at the base of the wings of the locust. Groups of eggs, young mites or their empty moults may be seen crowded together on their bodies. This mite was first noticed at Sandar-habr, and has, subsequently, been found in other places in the desert area. This mite has so far not been noted in Baluchistan, and the presence of a locust with a colony of this mite on its body at Ambagh among specurous collected during surveys made at the beginning of November, may therefore be taken as a presumptive evidence of the occurrence of migration.

8. Liberation of marked locusts,-The system adopted last year of marking the month and the fortnight of liberation on the wings of the locust with

cellulose paints and of tying coloured silk thread on the femora in addition, was followed during the current year in most of the locust observation stations at those times when locusts were present in good numbers.

During 1935 and 1936, altogether about 1,400 were thus liberated, but of these only 28 specimens, or about 2 per cent. have been recovered.

The details of liberation and recovery may be summarily shown as below:-

Y	Ceat.	Locality of hil eratio	Number liberated.	Number recovered.	Month of recovery.
		Westl	en Rek Are	15.	
1935	••	Pasni (about)	404	11	Jan., Feb., Mar., Apl., May and July.
1936	••	Pasni	136	3	March-May.
1933		Gwadar-Jiwani	63	1	October (4-5 miles).
1936		Ormara	18	nıl	
		Easter c	R Sunner R	AIN AREAS.	
1933	••	Ambagh	220	9	March, May, Sept., Oct November.
1935	••	Chachro	47	3	Dec., Jan., March
1936	••	Chachro	85	nıl	
1935	••	Barmer	100	nıl	
1935	••	Nokh	30	nıl	
1936	••	Nokh	205	1	November (about 1 mile)
1936	•	Sardarshahı .	15	rıl	

(Note -A full statement of the liberations made is given in Statement M.)

Of the recoveries made, only two cases were of real value viz., one captured at Rumra 20 mules off from Pasni on the 17th May 1935, and a second one recovered on the 2nd October 1936 about 4 or 5 miles from the place of liberation in the Gwadar Rek areas. It is rather significant that both these cases were during months when active ungration usually occurs.

In regard to the other cases of recaptures, they were all found not far from the place of liberation. It is rather noteworthy that many of these cases occurred during the winter months, when little migratory activity need be expected. The fact, however, that 98 per cent. of the locusts liberated were not traceable would indicate that at least some of the locusts released had migrated. As intensive surveys are being made only around the observation centres, and the touring staff are limited, the chances of the recovery of marked locusts in the vast sparsely populated spaces lying between

the centres of observation are rather remote. Mr. Batra reports that he tried a system of giving rewards to cases of recapture of marked locusts and circulated the information among the officers of the Lasbela State, but did not meet with any response.

In view of the importance of obtaining exact knowledge in regard to the direction taken by the migrants at different parts of the year, it would be advisable to intensify work in this direction.

9. Number of generations in the year.—It would appear that there was only one generation on the coastal areas of Mekran this year. In the interior of Mekran, the hoppers found in June-July at Thana Daragh were probably the second generation of the season. The hyaline-winged form collected in Kolwa in August is also probably an instance of the second generation, though there is no direct indication as to where the breeding had taken place.

In the summer rain areas, light breeding was recorded in Dera Ghazi Khan in April-May, as also to a slighter extent in the western reks of Lasbela and in the Mohangarh area of Jaisalmer.

In the Sind-Rajputana desert areas, the carliest adult of the first summer generation was observed as early as the 3rd August, and some of the adults of the first generation had laid eggs by the beginning of September.

The earliest adults of the second generation appeared in the course of October. A third generation should not be considered to be beyond the bounds of possibility, as a fair amount of rainfall occurred in November, but is rather improbable owing to the considerable drop in the diurnal temperatures.

- 10. Other locasts met with during surceys.—(a) Patanga succincta.—Mr. D. R. Bhatia collected a specimen of the Bombay Locust on the 7th November between Sonpalsar and Sardarshahr in the Bikaner States; and two more specimens on the 20th November at Girasar in cast Jaisalmer. The yellowish green colour of the stripes of the specimens collected was rather remarkable.
- (b) Locusts a migratoria ph. solitaria.—Quite large numbers were noticed in many localities in the summer rain areas this year.
 - 1. Kachhi area in Baluchistan Quite good numbers were noted in and Dadu District in Sind.

 July, as many as 100 specimens being observable in some Juari fields.
 - 2. Mallani area: 4 specimens in August.
 - 3. Thar area in Sind: 9 specimens in August-September.
 - 4. Jaialmer area; 22 specimens in November.
 - 5. Bikaner area: 10 in August, September and November.

It is rather noteworthy that specimens of the Migratory Locust should have been met with in the desert areas during the monsoon period, only and it would be rather interesting to find out whether this species also undergoes migratory flights in the "solitaria" phase.

The presence of large numbers of this locust in July among Juari fields is rather striking, and an investigation of its breeding habits should be useful in view of the recent expansion of agriculture in Sind.

IV.—Ecological Studies.

1. Meteorological and bio-climatic observations.—The results of the meteorological observations made during the year at Pasni, Ambagh, Chachro, Nokh and Sardarshahr are given in Statements F-I, F-II, F-III, F-IV and F-V respectively.

Pasni Locust Research Station.—A new meteorological area was laid out as per plan kindly furnished by the Agricultural Meteorologist, Poona and the screens and the various instruments were set up. The new additional equipment ordered for arrived in the course of the year and were set up in their places. The equipment included a Thermo-hygrograph, a Sunshine-Recorder (Whipple-Casella), Wet-maximum and Wet-minimum Thermometers, a Grassminimum thermometer, and an Assmann Psychrometer. The Anemometer was out of order during the greater part of the year, and as attempts towards repairing it failed, an order has been placed for an instrument of the latest pattern like the one used by the India Meteorological Department.

As decided at the Meeting of the Locust Committee this year, self-recording Hygrometers were ordered for the Desert Outposts at Chachro, Nokh and Sardarshahr, and have been in use since September-October.

- 2. Vegetational Studies.—Records have been made of the typical vegetation prevailing in the Mekran reks and the Rajputana desert areas by the Plant Quadrat method, and notes have been taken in regard to the appearance of the annuals. Much information has been obtained in regard to the food-plants preferred as food by the hoppers in the Sind-Rajputana area.
- 3. Locust Breeding at the various centres:—(i) Pasni.—The rainfall in the winter-spring season was below the average. Rainfall in January, February and March was 1.62", 0.83" and 0.96" respectively. The first hopper was observed on the 21st March, and the last one on the 18th May. The first adult of the new generation was found on the 18th April. The breeding was very much restricted.
- (ii) Ambagh.—In spite of a fall of 0.95" of rain in February, there was no breeding in the reks. During the monsoon, the rainfall was limited to 0.38" at the end of June and 1.32" at the beginning of July. There was no further rainfall during the year. The first hopper was noted about the middle of August, and the breeding was extremely limited.
- (iii) Chachro.—The first fall of the year was received at the end of June and amounted to 0.34". In July 4.62" were recorded, of which the main fall (3.87") was on the 1st July. 0.06", 1.25" and 1.22" were recorded during August, September and November respectively. The first adults of the new brood were collected on the 11th August, which would indicate that the first oviposition had occurred soon after the rain in June. Hoppers noted in October were apparently representatives of the II generation produced after the September rainfall.

- (iv) Nokh.—There were light falls amounting to 0.31" and 1.37" during June and July, which resulted in very light breeding. In August, very heavy falls of rain were recorded amounting in all to 16.36", of which the biggest fall was 5.01" on the 13th August. There were light falls in September and November amounting respectively and 0.69" to 0.84". Large numbers of hoppers were found in September and October, and a few also in November. The hoppers found late in the season represented the second generation.
- (v) Sardanshahr.—A fall of 0.84" was recorded on the 26th February. Rainfall in June and July was light, 0.70" and 0.92" respectively, and did not lead to any breeding. In August, there was a total fall of 2.74" and led to the emergence of a moderate number of hoppers in September. Hoppers were noticeable till the last week of October. There was very little rain in September, October and November.
- 4. Natural Enemies.—(i) An Avilid fly was found very common in the Rajputana desert areas during the monsoon months, and was found attacking and preying on various insects, among which the hoppers of Schistocerca and certain grasshoppers were included. From its active habits and its keen powers of sight, it would appear to be an efficient predator.
- (ii) At Pasni, a large black Sphegid was found chasing a locust on the wing, on 30th May, for nearly 5 minutes without eventually capturing it.
- (iii) As already mentioned, a Tyroglyphid mite was found parasitising locusts in the Rajputana area.
 - (iv) The following lizards found in the desert areas were identified :-
 - 1. Acanthodactylus cantoris cantoris.— Common in the Mekran reks and in the Sind-Rajputana areas. Attacks hoppers.
 - 2. Agama agilis.—Mekran reks; attacking hoppers.
 - 3. Agama minor.—Rajputana deserts.
 - 4. Calotes versicolor.—Rajputana deserts: the common "Blood sucker", or "Girghoot".
 - 5. Phrynocephalus ornatus (!) :- Mekran reks.
 - 6. Eumeccs schneideri: Pasni reks: V-instar hoppers found among the stomach contents.
- 7. Varanus griseus.—Common on the reks of Mekran and Lasbela.

 M2531CAR

PART II.

EXPERIMENTAL STUDIES ON THE LIFE-CYCLE OF THE DESERT LOCUST.

The following experiments were undertaken during the year mainly at Pasm, some of them being carried out in part also at Ambagh or Chachro:—

- The number of generations possible during the year under semi-natural conditions.—Pasni and Ambagh.
- The influence of the quality of food on the sex-maturation of the Locust.— Pasm and Ambagh.
- 3. The influence of the quality of food on the growth of the hoppers.—Pasni and Ambagh.
- 4. The food preferences of the Locust; Pasni for the 'rek' vegetation, and Chachro for the "desert" food-plants.
- The colouration of adults and hoppers in relation to the change of environment.—Pasni and Karachi.
- 6 · A str dy of the development of the eye-stripes among hoppers.—Pasni, Ambagh and Kar. chi.
- 7. The leagth of the incubation period under semi-natural canditions.
- 1. NUMBER OF GENERATIONS POSSIBLE DUTING A YEAR.—This year, the generation experiments were started with a pair that laid eggs on the 20th November 1935, as shown in Statement I-(a) from a reference to which it will also be found that on the 21th November 1935, a female belonging to the third generation had laid eggs and this started the fourth generation of the year. It is evident, however, that, in view of the approaching advent of cold weather conditions, the fourth generation would not be able to reach maturity till next February, so that practically under the conditions at Pasni only three full generations and a part only of the fourth should be deemed possible during the year. As may be evident from the figures given for Ambagh in Statement I-(a) the experience there this year has been similar.

In fact, as may be seen by a perusal of Statement I-(b) where the results of the last four years' experiments (1933—36) are given, four full generations have never been completed within 12 months in any year, and the utmost that can be conceded would probably be about 7 generations in the course of 24 months.

Notwithstanding the above considerations, there is the possibility that the locust, by virtue of its powers of long distance migrations, might be able to benefit by the vastly different conditions existent in distant regional areas to pass through 3 or 4 successive generations during the year in nature. For instance, during May-June, the conditions in the interior of Mekran would be very different from those of the coastal reks. Higher temperatures would be prevailing there at that time, and in places where rain had fallen, the conditions of humidity would also be optimum for development. Since in outbreak areas the gregatious hoppers have always been found among cultivation, the humid micro-climatic conditions of the Juatierrop should be quite favourable for the rapid growth of the hoppers, and the second generation of the locust may be expected to be completed much quicker than under caged conditions at Pasni.

Again, the migrants from Mekran in summer would, in the event of early rainfall, similarly find, on reaching the Rajputana area, conditions favourable for early growth and maturity, as had actually been noticed to have happened this year in the desert areas. On receipt of early thunderstorm rains between the 20th and the 25th June, egglaying had commenced elmost immediately with the result that fifth stage hoppers were noticeable by the last week of July and the earliest adults were seen by the first week of August.

Since one of the main factors in the causation of locust infestations is the development of conditions favouring rapid multiplication by bringing about a rapid succession of generations, it is important that the different generations as they arise in nature should be recognised and clearly distinguished. Under natural conditions, however, the same female may lay two or more successive batches of eggs at intervals, leading to the development of a hopper population of different ages, and ultimately bringing about an overlapping of generations, so that it is not an easy matter then to make a clear analysis of the situation. If, however, generation experiments of the kind under discussion were in progress at typical centres of the different regions, they would help one a great deal in reading the situation aright.

It is therefore suggested that, instead of starting the experiments at an unnatural time, they might be begun with pairs secured from nature at a time when under favourable conditions breeding might be expected naturally to begin in the area concerned. If carried through the season, as was done thus year at Chachro, they might be expected to give definite claes to the correct understanding of locust biedding in particular areas. This year, it is proposed to try this system at Pasni, the pairs being secured at the beginning of the breading season, viz., December-April.

Generation experiments on a large scale were also started early in the year in some of the field-cages, with the idea of determining how rapidly a mass population could be built up in the course of the year. The first generation had been followed, as also a part of the second by April-May, when they came to an abrupt end on account of the persistent inroads of ants inside the cages, which could not be checked in spite of treatment with calcium cyanide.

II.—EXPERIMENTS ON THE INFLUENCE OF THE QUALITY OF FOOD ON SEX-

Statement G-I shows the results of the experiments carried out in the summer of 1935 and included in last year's report, and G-II the results of the autumn of 1936 (which were yet incomplete last December). During 1936 the experiments were restricted as recommended by the Locust Committee to the important food-plants of the locust, and to comparative observations on the effect of fresh and old Marrand and of fresh and old Kharzan. The results of the summer 1936 set of experiments at Pasni are given in Statement G-III, while those of similar experiments conducted at Ambagh with Kharzan, Balibur and Juari during 1936 are given in G-IV. In addition, females kept in cages improvised with a large glass chimney and wire-gauze were fed on the different plants at Pasni, and the facces passed by them each day were separately collected and weighed after drying them in a water-bath. The results of this experiment are shown in Statement G-V.

The results noted in Statements G-I, G-II, G-III and G-IV have been tabulated below for purposes of comparison.

N.B.—In the Table given below 'A' stands for the "Time taken for the development of yellow tings in the wings: (in days)", and 'B' signifies "Time taken for the first oviposition (in days)".

Recial Nature of Food Time A B Pasm Summer-35. Autumn 35 Summer-26. Ambugh 1076	
1 Fresh Marrand A 17.6 18.8 10 25 2 Old Matrand A 25.3 24 17.3 B 43 1 90 54 2 Jowari A 10.7 13.7 27 B 22 3 45 36 4 Jowari Seedlings A 10 7	Remarks.
B 35 45 37 2 Old Marrand A 25·3 24 17·3 B 43 1 90 54 3 Jowari A 10·7 13·7 27 B 22 3 45 36 4 Jowari Seedlings A 10 7	
2 Old Matrand A 25.3 24 17.3 B 43 1 90 54 3 Jowari A 16.7 13.7 27 B 22 3 45 36 4 Jowari Seedlings A 10 7	
B 43 1 90 54 2 Jowari A 16·7 13·7 27 B 22 3 45 36 4 Jowari Seedlings A 16 7	
3 Jowari A 10.7 13.7 27 B 22.3 45 36 4 Jowari Seedlings A 10 7	
B 22 3 45 36 4 Jawari Seedlings A 10 7	
4 Jowani Seedlings A 18 7	
B 34 25	
	
5 Maire A 13	
В 35	
6 Kharran A 23.7 35 27 18	
B 59 5 88-6 51 35	
7 Old Kharzan A 16	
B 39	
8 Balibur A 24.8 41.5 20.5 16	
B 40 104 63 50	
9 Kulinkk A 21.5 68 33.2	
B 38-5 100 64	

The above results would show that Sorghum (Jowari), Maize, and Jowari seedlings top the list and that Fresh Marrand comes an easy second. It may be noted that while Kharzan has given poor results at Pasni, at Ambagh it has proved as good as Fresh Marrand, and even Old Kharzan has given good results. Balibur too has given slightly better results at Ambagh, and possibly in the Sind-Rajputana areas, where it flourishes best it may show better results.

In regard to the experiment in which the relative quantity of the exercts of female locusts fed on the different food-plants have been determined, it is unfortunate that most of the females should have succumbed to the scorching blast of the dry "Gorich" wind that was recorded at Pasni on the 21st October raising the air temperature to 107° F, so that no records of oviposition could be made. The results recorded in Statement G-V, however, show that n the case of Marrand, Balibur and Kharzan, and especially in the case of

Old Marrand, the average weight of faces excreted per day per insect is almost twice as great as that of Maize or Jowari. This is only what might be expected, since Marrand, Balibur and Kharzan have weight for weight a much greater percentage of indigestible matter in the shape of spines and hairs than Maize and Jowari, the differences in the water-content not being relatively very considerable. Consequently, the proportion of roughage being greater, a larger quantity of these plants have to be eaten to get the same amount of nutriment as Maize or Jowari leaf. Possibly the greater effect of the Jowari leaf is due to its being more nutritious. The figures of the average shown here are, however, based on the weights worked out for two locusts for each plant, and it would be desirable to have the experiments repeated to secure results of greater reliability.

III,—Experiments on the inpluence of the quality of Food on the Growth of the Hoppers.

About 30 just-hatched hoppers were kept in the chimney cages above mentioned and fed on the different food-plants, and the faces passed out by the hoppers of the same stage were carefully collected every day and weighments made after being dried in a water-bath. It was found that all hoppers fed on Jowari, Kharzan and Balibur died in the first stage at Pasni. As in the case of the adult females, the greatest amount of faccal matter was excreted by the hoppers feeding on old Marrand, and the least by those on Maize. Owing to the occurrence of the "Gorich" on the 21st October, a good many of the experimental hoppers perished and many of the experiments were unfortunately cut short.

At Ambagh also experiments on breeding the hoppers on the different food plants were made, but the hoppers were bred individually in separate cages, and no attempts were made to preserve the excreta. At Ambagh, hoppers were successfully reared on Jowari, Kharzan, Balibur and Marrand, and it was only in the case of Mazoung, most of the hoppers died. The relative length of the larval period in the case of the various food-plants is given below for comparison:—

Locality.	Fresh Marrand.	Old Marrand.	Kul- lichk.	Bah- bur-	Kharzan.	Old Khar- zon.	Maire.	Jonari Serd- lugs.
PA9NI.					,			
Average Length of Larval period.	46·8 4eys.	53.8 days	66·3	all died	all died	••	87.5 days	ill died.
Shortest period	38 days.	50) days.	60 days	••		••	52 days.	
ANBAGH.								
Average Length of Larval period.	52 days.	٠.	••	62.7 days	47-5 days.	51 days	••	40-5 days.
Shortest period	43 days.		••	45 days	37 days.	40 dayə.		31 days.

The details of the hopper-feeding experiments at Pasni are given in Statement, II-I, while those at Ambagh in Statement II-II.

The percentage of the water-content of the various plants used for food experiments at Pasni was worked out and the results are given in Statement II-III. Of the determinations made, the figures given for Jowari Plant, Jowan seedling and Bajra appear to be rather low, and may be due to the poor quality of Jowari, and Lajia seedlings available in the neighbourhood of the Pasni Research Station, as the soils in the vicinity are agriculturally very poor, and the specimens of seedlings obtained for feeding were lanky and thin. It would be advisable to have further weighments made of good specimens.

In future experiments, it would be advisable to calculate separately the length of the hopper period for those undergoing extra moults, as the latter contributes to the prolongation of the larval period by about a week or more.

N. B -Mr. Ta it Alian was rea on this for the food experiments at Pasni

IV.—FOOD PREFERENCES OF THE LOCUSTS. . .

1. Mekran Rek Arcas.—In order to test the preference of the locusts to particular food-plants, Dr. M. L. Roonwal performed a number of experiments, by trying some of the commonest plants found on the Mekran reks as food for hoppers and adult locusts.

In these experiments, cage-bred black hoppers of various stages, excluding the first instar, were liberated in a wiregauze cage 3 ft square and 3 ft. high fitted with a plank bottom. Twigs of the food-plants were placed in small dishes of water, which were arranged in a circle on the floor of the cage. The hoppers were partually starved before the start of each experiment, which was repeated several times, readings being taken at discrent times of the day and with the same set of plants arranged differently. In this way, chance errors due to phototropism and other causes were eliminated, as far as possible. In each experiment, two counts were taken as a rule, one 15 minutes after the introduction of the hoppers, and the second, about half to one hour later. Notes were made as to the number of hoppers on each food-plant and as to whether they were feeding or not, and the number of hoppers found on each different plant was taken as a measure of the preference of the insect for the particular plant. The results of the various experiments are given in detail in Statement J.

The net results may, however, be shown in the following table, wherein the plants have been arranged in the order of preference by the locusts:—

Serial No	Common Name.		Scientific Name.		Abbreviation used	Remarks
1	Vioixe .	•••	Tea mays	•••	z	No clear preference be
. 2	Bajra	٧.	Pennsselum typhoideum	••	P	tween (1) and (2)
3	Kulliohk		Cyperus arenarous	••	c	No clear preference be-
~ 4	Marrand	••	Heliotropium undulatum	••	M	tween (3) and (4).
5	Jowan	٠.,	Andropogon eorghum	••	J	
6	Kbarzan	••	Sericorii ma pauci torum		~- к	
7	Balıbur	••	Aerua sarantea		В	
8	**************************************		Sphaeroroma Hoolers		s	

It was found that while Marrand is preferred to Jowari by the hoppers the adults show greater attraction to Jowari than Marrand. Dr. Roonwal thinks that it is desirable that further experiments are needed especially in regard to green hoppers and adults.

2. Plants of the Indian Desert areas.—Mr. D. R. Bhatia performed several experiments at Chachro in August and October to find the order of preference shown by hoppers in regard to various plants—cultivated as well as wild usually met within the desert. Fresh specimens of the various food plants were obtained and placed at the bottom and hoppers, either I—stage hoppers or those of the V-instar, were introduced. After 5 hours or more, during which the food-plants were shuffled more than once to eliminate chance preferences, the leaves were examined to find out the extent to which each plant had been eaten.

The following is a general statement of the results obtained by him :-

- I.—Plants absolutely refused.—'Ak' (Calotropis) and 'Neem'—
 Azadi rachta indica, were not eaten by hoppers even after several
 hours' starvation, though the adults ate them a little under the
 stress of starvation. The 'ovules' of Ak flowers were, however,
 found eaten. Other common plants found refused, though not
 absolutely, were: Bordi (Zizyphus), Bavuri (Acacia sp.), Murant
 (Panicum turgidum), Jhal (Salvodora persica), Lampdi (Aristida
 sp.), Chibar (Cucumis trigona), Tursan (Citrullus colocynthis),
 etc.
- II. Plants preferred best.—Among the cultivated plants found in the desert areas, Kaling (Water-melon—(Citrullus vulgaris), Bajra (Pennisetum typhoideum) Til (Sesamum indicum), Moth (Phascolus aconitifolius), Gwar (Cyamopsis psoralcoides), and among the wild vegetation, Wekra or Bekkar (Indigofera cordifolia), Bishani (Tephrosia Hookeriana), Kanti (Tribulus terrests is), Bharut (Cenchrus catharticus), Bagra (Gynandropsis pentaphylla), Santa (Trianthema pentandra), Gamol (Panicum antidotale) and Siwan (Elionurus hirsutus), etc.

Next in order of preference, the following are reported:—Booh (Aerua javanica), Gandhil (Dactyloctenium scindioum or Eleusine aristata), Bhengri (Blepharis sindica), Phog (Calligonum polygonoides), Kuri (Brashiaria sp.), etc.

Other plants were but slightly eaten.

Experiments also showed that among the preferred plants, semi-dry plants or specimens which were over-mature were forsaken for others, usually not much liked, if in a green state. The order of preference shown by the experiments was found actually confirmed by observations made in the descrt this year. For instance, Wekra and Kanti were usually preferred to Booh when they were in a green flourishing condition, but in October-November when they had become semi-dry, hoppers were found mostly on Booh.

It would be necessary to repeat some of the experiments next year and have the results confirmed.

V. COLOURATION OF ADULTS AND HOPPERS IN RELATION TO A CHANGE OF ENVI-

Observations made in nature would show that hoppers found in the field usually assume the general colour of the vegetation in which they happen to live. Those found on Booh (Acrva), and Kanti (Tribulus) are seen to have a bright ashy blue colour, while those found on Wekra and Marrand are light to dark green. Some found among drying grass have been noted to have a yellow brown or hay colour. Certain field observations made would suggest that such a change of colour usually takes place just after a moult, the colouration of the environment of the time being, being assumed by the hopper. Possibly the colouration of certain hoppers found in nature showing patches of brown on a background of green, is also to be ascribed to such a circumstance.

Dr. Roonwal performed a set of experiments rearing hoppers in small painted boxes, the results of which are given in his own words in Statement O.

The results obtained would seem to show that the colours that can be simulated are limited by the range of colouration tints that can be expected to be found in their natural environment.

In regard to the adults, it has also been noted that locusts recently transformed from the hopper stage usually show the hopper colouration on their prothorax, there being a pattern of light dots on a darker background, without the dorsal and lateral stripes of the adult. At Karachi, it was found that if kept in the shade this colouration persisted for more than ten days, while specimens kept in the sun assumed the stripes fairly soon. Similarly, the eyes of fresh adults transformed from black-coloured hoppers are usually a uniform brown generally without stripes, or if at all, with the stripes very faint. Experiments performed at Pasni (vide Statement L-II) have shown this year that in specimens with unstriped eyes kept in the sun, light coloured interstripes gradually appeared converting the eye into a striped one, while in the locusts kept in shade there was no such development. Presumably the stripes are present in all locusts, whether gregaria or solitaria, and are only masked by a superficial cover of brown. Among the ashy-blue hoppers found on Booh (Aerua) the eyes are masked by an ashy-blue colour in which the stripes are seen as faint streaks.

Possibly the appearance of the dorsal stripes and the accentuation of the brown and light patches on the body, as well as the appearance of the eyestripes have the purpose of making the locust less conspicuous in its natural environment among the scrub vegetation of the "reks". This year a number of locusts with a bright green tinge on the dorsal stripes and on parts of the elytra and thorax were found in August and September in the Rajputana area. Similar forms were also collected in the Lasbela area in July among bright green grassy vegetation. At first, these specimens were thought to be abnormal young forms of the new generation whose chitin had not hardened, but the individuals collected in the Lasbela area were clearly specimens of the migrants found in June, and there was little doubt that the green colour had been recently assumed. It is also remarkable that these green forms could not be seen in October-November when specimens having the dry-grass colour were greatly in evidence. Again, very dark-coloured specimens have in

the past been collected in the 'siah-pat' or black gravel areas of the Mekran hinterland. These instances would appear to indicate that the adult form of Schistocerca is possessed of the ability to change its general colouration to a certain extent to suit its environment.

VI.—A STUDY OF THE DEVELOPMENT OF EYE-STRIPES AMONG THE HOPPERS.

In January of the current year, Dr. M. L. Roonwal discovered in the course of an examination of locusts collected in the field that there were two main types of eye-stripes among the Desert Locust specimens met with on the Mekran reks, one with sir brown stripes and the other with seven. A note on this discovery was published by him in July 1936 in Current Science, Vol. 5, page 24.

With the idea of tracing the development of the eye-stripes in the hopper stages, he followed the rearings of more than 120 isolated hoppers and found that stripes were present in green hoppers even in the first instar. After tracing the development of the stripes in the hoppers, he has come to the following conclusions. As a general rule one stripe is added in each stage of the hopper. The anterior margin of the eye functions as the active growth-region, and the growth of a new stripe takes place during the interval between successive moults. There are two distinct types of development of the eye-stripes. Until the second stage, the development is identical, there being one additional stripe for each moult. In the third stage, only one stripe is added in the six-striped eye, and two in the seven-striped type. In all the subsequent stages, one stripe is added at each normal moult (vide Statement P-I). The two types of development may be schematised as below:—

Fingo	I.	11.	III.	IV.	v.	Adult.
Number of stripes	1	: {	3 4	4 8	ភ 6	6

The number of stripes and interstripes during extra moulting may either remain the same or increase by one (vide Statement P.-II).

Since the eye-stripe difference is not confined to the adult stage, but extends to the earlier hopper stages (appearing in lots bred under exactly the same conditions), Dr. Roonwal has come to the conclusion that the difference is a deep-seated one.

With the idea that the difference might be a genetic one, he tried crossings between the two types, and is awaiting the emergence of the F.-2 generation for coming to some decisive conclusion.

At Karachi, Dr. S. Mukherji undertook, under my instructions, some breeding experiments to find out if the difference in the st-ipes could be due to the amount of sun-light to which the hoppers had been subjected during the stage M25HOAR

of their growth. Accordingly a dozen hoppers were kept individually in small wiregauze cages and exposed to sun-light in the open, and another similar set kept in shade inside the office. Two sets of rearings were gone through, but little difference could be found between the hoppers kept in the sun, and those in the shade, so far as stripes were concerned, though those kept in the sun were quicker in development and were healthier. Many of the hoppers kept in the shade died. Incidentally, however, the rearings have proved very interesting, since (as may be seen by a reference to Statement P.-III) his observations would appear to show that the number of stripes in the eye vary directly with the number of moults undergone by the hopper. In all cases of extra moults, he found seven stripes appearing; where there were no extra moults, the number was six; and in one case, an abnormal adult was produced that went through only four instars and had only 5 eve-stripes. He found that, without any exception, one stripe was added at the end of every moult passed through by the hopper.

Mr. R. N. Batra also made observations at Ambagh on the development of eye-stripes in hoppers in the course of his experiments in regard to the effect of Quality of Food on hoppers, and he also found a correlation between the occurrence of the extra moult and seven stripes in the adult (vide Statement H-II).

It appears, therefore, necessary that further work should be done for getting a more definite enlightenment on the development of the stripes.

Forms with 8 stripes were found in the Bikaner area occurring in nature, and an examination of the forms has not revealed any abnormality in their structure, while in the course of rearing at Karachi, nearly 50 specimens with 5 eye-stripes were found to have developed in the cages under conditions of crowding. Some of these were deformed and had crumpled wings, but others were perfect in the proportions of wing and body, but were undersized. These forms were isolated in a cage, and laid eggs. The hoppers that hatched out have developed into healthy hoppers, which have reached the IV and instars and show promise of developing into normal 6 or 7 striped adults.

VII.—THE LENGTH OF THE INCUBATION PERIOD UNDER SEMI-NATURAL CONDI-TIONS.

The shortest period of incubation so far observed under these conditions was recorded this year, viz.. 12 days.

The details are given in Statement K.

PART III.

STUDIES OF OLD RECORDS: MISCELLANEOUS ITEMS: CONCLUSIONS. I.—LOCUST MOVEMENTS IN THE YEAR.

Four reports were received during the year, but all of them were found to concerned with various species of Acrididæ. No swarms were reported observed anywhere during 1936.

1. 9th to 11th June 1936.—Report to he Imperial Council of Agricultural Research from the N.-W. F Province.

Hoppers were reported to have appeared in villages in the Peshawar Tahsul. On investigation by the Province. Entomologist of the Frontier Province, the hoppers concerned were found to be those of This sorcetrus, Coloptenopus, and Calantops spp.

- 31st August, 1936.—Report to the Imperial Council of Agricultural Research.
- Grass-hopper swarm attacking Fodder Juar in the Anarad village of Dhar State. Specimens sent proved to be Hieroglyphus nigro-repletus Bol.
- 3. 17th July 1936
- L. Specimens of a swarming Aeridid—Aularches miliaris
 L. reported attacking thatchbarres in Kumargram
 Tea Estate, Jalpaiguri, Assam; from the Chief
 Scientific Officer, Indian Tea Association, Connemara.
- 4. 20th October 1936
- .. Grasshoppers attacking the cotton crop and gram sprouts in Manyer Tahsil of Kushalgarh Chiefship. Proved to be species of Acrolylus, Oed cleus and Caloptenopsis.

II.—STUDY OF OLD RECORDS.

During the year under report, most of the chronologically arranged data for the years 1926 to 1930 were gone through and edited for final typing. Data for the years 1926, 1928 and 1929 have been typed and are ready for being forwarded to the Imperial Council for printing, as suggested at the last meeting of the Locust Committee. The records for 1927, 1930 and 1931 will be taken up shortly.

The maps so far done were examined and compared as far as possible. Six-monthly maps for the years 1926 to 1930 were also prepared.

III.—Correlation of Meteorological Data.

Indian Daily Weather Reports for the years 1926 to 1931, and 1932 to 1935 were taken on loan, in batches, from the Meteorologist, Karachi, and studied in correlation with the development of the locust situation in those years. The main points under study were the following: 1. The development and progress of summer and winter rainfall in each particular year for correlating the known facts of locust infestation and breeding: 2. Data in regard to the development of zones of high temperatures and low humidity in the winter-rainfall areas in early summer, and in the monsoon areas in autumn in relation with the recorded direction of swarm migrations during the cycle of 1926-1931; and 3. The correlation of the direction of swarm flights with the recorded direction of wind.

The results of the correlation of the wind directions have been particularly interesting. Though cases of differences of directions have been noted, there has been, on the whole, a remarkable preponderance of coincidences of directions. As far as possible, attempts have been made to show the direction of winds on the monthly maps for the different years. In one case, especially, the coincidence was rather very striking. While in the first part of June 1930, the flight of locusts was towards the east and the wind directions were also in general west to east in the United Provinces, the directions of the swarms as well as the winds had changed in the latter half of June 1930, with the development of the monsoon current, from east to west, so that by July 1930, the eastern parts of the United Provinces were clear of locusts.

During the last locust cycle, it is seen that in the years 1928 and 1930, west-bound flights were not noticeable in Baluchistan in the autumn months, while during the years 1926, 1927, 1929 and 1931 they were clearly well developed. A study of the situation in the months of September, October and November in regard to the meteorological conditions in the Rajputana area was made in these years, and the results obtained indicate that the absence of the west-bound flights in 1928 and 1930, was very probably due to the delay in the development of the north-easterly winds in the autumn, so that most of the swarms produced had departed from Rajputana in other directions. Table A has been prepared to show the situation in the western and eastern areas of infestation during 1926-1931 in regard to the development of zones of saturation deficiency.

TABLE A.

Development of areas of High Saturation Deficiency in regions subject to Locust infestation during 1926—1931.

Western zone in May-July.	Eastern zone in September-October and November.
VVII.—1926—Development of high temperatures and low humidity occurred in the areas of Dalbandin, Mirjawa and Panjgur, (there being 3 pc als.). (1) 20—27-V, (2) 13—19 VI and (3) VII. (05—109°; (101°—113; (102—117, 13—60%) 8—50%) 12—60%).	1926. September was fairly humid and cool. October.—The dry rone developed and N., N. E. and E. winds prevailed at the beginning and the middle of the month. Notember.—Low humidity—generally E. winds prevailed. As swarms developed mostly in October and November, migration we-tward also resulted.
F.PH-1927(Tuo peaks) (1) 20-27 V (2) 23-30 VI and (98~-110°; 5-45%) 11. (99~-116° 39%-70%)	1927. Morsoon continued till Ist week of October. September.—Dry rone developed: 18—24 iX · Lasterly winds began by the end of the month October.—Max: 92—99: Humidity about 35% to 60% S. W. winds generally prevailed. Notember.—Humidity low: L. winds prevailed towards the middle and and of month. (l'anourable for westbound flights)
V-VII-1928(3 peaks) (1) 22-31 V (2) whole of VI (102°-111°; (100°-114°; 16-50%) 8%-60%) and (3) whole of VII (04°-113°, 12-70%).	Monsoon continued into October. September.—Tarrly cool and morst: mostly S. W. winds October.—Dry zones developed during the first half of month, but the winds were mostly S. W. Notember.—Low humidity prevailed: Easterly winds from 12th November onwards. (Conditions unfavourable till November 12th for westward flights.)

Western zone in May—July.	Lastern zone in September-October and November.
7-1/11—1929.—(Three peaks) (1) 19-31 V (2) whole of VI (90'—111°; (100°—115°; 16—50%) 9'%-90%) and (3) whole of VII (97°—114°; 5—50%).	Monsoon strong. September.—Dry rone developed from 16th September but mostly S. W. winds prevailed. Orlober.—Humidity generally low. N. E. winds prevailed on 4—6 X and from 16th October for a few days oft and on. Northber.—Humidity low as also maxima: N. E. winds generally prevailed. (Breeding being at its maximum, both west bound and east bound flights took place.)
V-VII.—19:0 (4 peaks) (1) 6—11 V (99°—114°; 16—60°;). (3) 5—30 VI (97°—114°; 13—75%). (2) 27—30 V (95°—105°; 20—17°;). and (1) whole of July (98°—116°; 8—70%).	Moneoon withdrew early about III week of September, breeding elso early. September,—Dry zone developed early; 107° max., and Humidity 43%. But winds mostly S.W. or W.S.W. October,—Dry zone prevailed with high maximum temperatures; E. winds started only from 20 X and continued till 30 X. Norember,—Humidity low. East winds prevailed. (Directing was early and most of the swarms appear to have departed eastward already.)
V.VII 1931.—(3 peaks) (1) 17—21 V (2) 7—20 VI and (97°—108°; (05°—114°; 5—56°,0). (3) whole of VII (90°—108°; 9—60°,0).	1931. Moneoon withdraw only about 17th October. September.—Dry some developed from 18th September. E. winds from 20th September. October and Novenber.—Maxima lower: D. winds prevailed generally. (Weetward migration occurred though late.)

IV .- Publications.

A paper on "The Locust Incursion of 1935 in North-West India—Its Significance in the Study of the Locust Problem in India" was sent by me to the Journal of Agricultural Science and was published in the October 1936 issue. Two papers were, under instructions, submitted in March to the IV International Locust Conference at Cairo, viz., 1. "Migration among the Solitaries" and 2. The occurrence of Incipient swarming in Mekran". A note by Dr. M. L. Roonwal on "The Existence of two different types of striped eyes among solitary type individuals of the Desert Locust, Schistocerca gregaria, Forsk." was published in July 1936 in "Current Science", Volume V, page 24.

Two Bulletins on the Desert Locust by S. A. Predtechensky published in 1935 in Russian were kindly sent by Dr. B. P. Uvarov at the close of 1935, and arrangements were made to have them translated. One of them, viz.,

generation, the tendency is to produce the higher ratios and six-striped forms. In case there is a general correspondence between the number of stripes and the number of moults passed through by the hoppers, the eye-stripe character would become a valuable index in judging about the likelihood of swarming in any given area, since the number of moults would be fewer when rapid multiplication takes place.

In regard to the presence of stripes in other species, it is interesting to note that the number of stripes is either 7 or 8, in the specimens of Patanga succinata in the Karachi collection, 8-striped forms being. however, more common. In the single specimen of Nomadacris septemfasciata kindly presented by Dr. Uvarov, for the Karachi collection, the number of stripes is 7. It is rather significant to note that both Patanga and Nomadacris are known to pass through at least six moults as a rule. Specimens of Anacridium in the collection have either 7 or 8 stripes, as also those of Cyrtacanthacris tatarica. As already mentioned, about 6 specimens of 8-striped forms of Schistocerca have also been met with in nature this year.

VII.—MISCELLANDOUS ITEMS.

- 1. Pasni Buildings.—The buildings were completed at the beginning of the year, and occupied by the staff.
- 2. Large Field Cages.—Only four of the eages were in use during the year but their usefulness was greatly affected by the inroads of ants. Again, owing to the high humidity and the heavy winds prevalent throughout the year, and the formation of thick fogs and mists, and the accumulation of fine clay dust among the meshes, the copper wire gauze used for the sides of the cages has already perished in many places, and may require replacement.
- 3. Distinguished Visitors.—The office at Karachi had the honour of a visit on the 1st September 1936 by Sir Bryce Burt, Kt., C.I.E., M.B.E., I.A.S., Vice-Chairman, Imperial Council of Agricultural Research.

On the 2nd December 1936, Sir John Russell. O.B.E., D.Sc., F.R.S., Expert Scientific Adviser (Crops) to the Imperial Council of Agricultural Research accompanied by Lady Russell, Mr. R. L. Sethi, Secretary-Adviser, Rao Sahib K. I. Thadani, Offg. Chief Agricultural Officer in Sind, and myself paid a visit to the Ambagh Locust Research Station, in Lasbela State. On the 3rd December. Sir John Russell paid a visit to the office at Karachi for discussing the locust work.

- 4. Supply of locust specimens for experimental work at Lyallpore.—At the request of the Government Entomologist, Punjab, locusts collected from Ambagh were supplied in May, and in September specimens of locusts and hoppers collected from nature in the Bikaner areas were handed over to a Fieldman. In October, a third consignment collected from nature at Ambagh was supplied.
- 5. Information regarding the Iranian and Persian Areas.—As decided at the Locust Committee, a questionnaire in regard to the information required concerning locusts and locust breeding in the areas of Iranian Mckran, and the Arabian Coasts of the Persian Gulf, was prepared and submitted to the Imperial Council of Agricultural Research, for circulating to the authorities concerned.

VIII.—ACKNOWLEDGMENTS.

Ready and whole-hearted help kindly rendered to the Locust Survey Staff during their tours in connection with locust research work by the various authorities in Sind, Baluchistan, Rajputana, the Punjab States and the Punjab, and by the Durbars of Kalat, Las Bela, Bikaner, Jodhpur, Jaisalmer, Bahawalpore and Khairpur States is hereby thankfully acknowledged. The thanks of the Imperial Council of Agricultural Research are specially due to the Durbars of Kalat, Las Bela, Bikaner, Jodhpur and Jaisalmer for facilities provided to the staff at the Locust Research Stations opened in their territories. I take this opportunity of thanking Mr. V. V. Sohoni, B.A., M.Sc., Meteorologist, Karachi for the various facilities and help provided to me in the study of meteorological data in relation to locust work. My thanks are specially due to Dr. L. A. Ramdas, M.A., Ph.D., Agricultural Meteorologist, Poons for help and advice in regard to the purchase of various meteorological instruments. I wish to place on record my indebtedness to Sir Guy A. K. Marshall, C.M.G., F.R.S., Director, Imperial Institute of Entomology and Dr. B. P. Uvarov, D.Sc., for kindly identifying various insect specimens and for other help rendered. My thanks are due to the Curator, Royal Botanical Garden, Sibpur for kindly naming several lots of plant specimens.

I have to place on record the good work done by Mr. Chandar Parkash. B.Com., till recently Senior Compiling Assistant at Karachi, who was appointed at the Imperial Institute of Sugar Technology, Cawnpore at the beginning of October. He was of very great help to me in extracting information from various records, mapping the locust movements, and studying various meteorological data. The loss of his services and his experience has been a great handicap this year. The section also lost the services of three efficient hands in the clerical line by the transfers of Messrs. R. L. Mehta, Shafkatullah, and Abdul Halim (Clerk at Pasni since 1932). I wish to express my thankfulness to Dr. Roonwal, Dr. Mukerji, and Messrs. Bhatia, Batra, Taqi Ahsan and Rashid Ahmad for enthusiastically carrying out their work through out the year.

IX.-CONCLUSIONS FROM THIS YEAR'S RESULTS.

In comparison with last year's happenings, the year under report has proved somewhat uneventful in regard to locust developments. On account of the lower rainfall this year on the Mekran Coast of British Baluchistan, and even in the Iranian areas, except at Bushire, the breeding was very much restricted. Nor was any breeding of any consequence noticed in the interior of Mekran. In spite of the low rainfall, however, there were evidences of secondary breeding in the hinterland. In Kolwa, a development of gregarious hoppers was reported even during the first generation, and in June-July a small breeding representative of the second generation of the season was noticed near Panigur.

Secondly, the present year's observations have confirmed last year's findings in regard to the occurrence of a migration of the solitary locusts. Arrival of migrant locusts was noticed in early summer almost at the same time at Pasni, Ormara, Ambagh, and Chachro. Evidence of a return migration in the autumn months was also obtained at Ambagh, Ormara and Pasni.

Experiments with the marking and liberation of locusts has not so far given any definite results, but that would appear to be due to our ignorance as to where we should expect the liberated locusts to go to. There appears to be little doubt that locusts would be carried by the prevailing winds, and that they cannot be expected to fly against any wind of some force. The locusts that were noticed at the end of May this year almost simultaneously at Pasni, Ormara and Ambagh could not have taken a direct west-to-east direction. It is more probable that they had been carried from the coastal areas into the Mekran interior by the S. W. wind and had later on been deflected south by the unsuitably dry climate of the interior.

Possibly, the earliest locusts usually arrive in the Desert area with the S.W. wind in the region of Khairpur, Bahawalpore and north Jaisalmer, and reach the southern areas of Marwar and Thar-Parkar only later on with the development of winds from the N. W. or from the N. E. at the time of the appearance of depressions in the Rajputana area. On this account it appears to be important to keep watch over the areas of Kachhi, N. Sind, Khairpur and Bahawalpore at the beginning of the migration season in May-June.

Thirdly, on account of the heavy rainfall in the Bikaner Jaisalmer area this year the breeding in the desert has been fairly early and heavy, though in the south in S. Marwar and Thar areas, the breeding has not been extensive. In the northern areas, the development of two successive generations has been noticed. During November and early December, quite large numbers of locusts have been noticed in the north Jaisalmer, Bikaner and Bahawalpore areas, which do not seem to be likely to migrate now, owing to the onset of the winter conditions, when there is usually no urge from climatic considerations to quit the desert area. It is necessary therefore to watch their further movements, to see whether they will move west or east in spring. On account of the limited nature of the survey staff, it has not been possible to find how far east the solitaries would penetrate.

The study of the meteorological data and their correlation with locust data has been productive of much useful information, and the fact of the coincidences of wind directions is a very important advance in our knowledge.

The discovery of the eye-stripes should also be considered an important advance as it may lead to important inferences if worked up more fully.

The food-experiments also appear worthy of being followed up.

PART IV.

SUGGESTIONS FOR FURTHER WORK.

At the last meeting of the Locust Committee, it was decided that Locust observation work and a locust warning organization should be continued on a permanent or semi-permanent scale under the Government of India, and in case any permanent arrangements have been made, the future of the work might best be settled by the Imperial Agricultural Department. Suggestions made here are on the basis of a continuation of the present organization, and might therefore be modified as needed.

My recommendations are that the work might be continued on the same scale with more or less the same staff, with the following few additions.

M263ICAR

- 1. Pasni.—One of the Messengers was transferred to Panjgur when that Outpost was created, and on account of the increase of biological experiments at Pasni, it is desired that a messenger on Rs. 12 might be added to the staff.
- 2. Karachi.—Last year it was suggested that food experiments with the Sind-Rajputana desert plants might be conducted at Karachi. I should bring it to the notice of the Imperial Council that at the place where the office is located, there are few facilities for growing the desert plants and conducting the experiments. Shifting the office to a better locality with facilities for growing plants would mean renting a suitable building, which would lead to further expense. I should, therefore, suggest that they might be performed either at Ambagh or Chachro, where the plants might either be grown or perhaps be secured from the surrounding desert.
- 3. Sind-Rajputana Arca.—As already stated, the Khairpur-Bahawalpore-Kachhi area is important as the earliest migrants—whether as swarms or individuals—are likely to be met with here. Last year, one of the Fieldmen was posted at Khairpur with the Imperial Council's permission for six months. As this arrangement disturbed the work at Barmer, I should suggest that a Fieldman and a messenger be added for being posted at Khairpur throughout the year.
- 4. In case the transfer of the present organization under the Imperial Department be completed, my services would no longer be needed for guiding the work, but since there is yet a great amount of work to do in regard to the working up of the results of the last 6 years for purposes of publication, and also with reference to the completion of the biometrical and compilation work, I should request that my services may be continued for the next year for this purpose.

KARACHI; Dated the 27th December 1936. Y. RAM CHANDRA RAO, Locust Research Entomologist, Karachi. A NOTE ON THE RESULTS OF THE WORK DONE UNDER THE LOCUST RESEARCH.

SCHEME OF THE IMPERIAL COUNCIL OF AGRICULTURAL RESEARCH DURING THE YEARS 1931 TO 1936.

THE AIMS OF THE LOCUST RESEARCH SCHEME.

The aims of the Locust Research Scheme as initiated in 1930 may be considered under the following heads:—

- 1. Studies on the Bionomics of the Desert Locust;
- 2. Experiments on the Control methods;
- 3. A survey of the permanent breeding grounds within the limits of India;
- 4. An ecological study of the solitary phase in its breeding grounds; a study of the fauna and flora in these areas, including an investigation of the natural enemies of the locust as well as its food-plants;
- 5. A study of the migration routes of the Locust in the Indian area;
- 6. A correlation of the meteorological factors; and
- 7. A study of the past invasions.

The first of these items has been under study at the Locust Laboratory at Lyallpore, and the second could not be taken up as the swarms disappeared after 1931. The rest of the items have been under study by the staff under a unit, first stationed at Quetta and, since June 1933, at Karachi.

The results so far obtained during the last six years under the different items are attempted to be set forth briefly in this note.

I.—Survey of the permanent Breeding Grounds within Indian limits.

Surveys of the Baluchistan areas were first taken up in 1931, resulting in the detection of the "Rek" breeding grounds along the coastal areas of southern Baluchistan. This led to the establishment of a Locust Research station at Pasni in January 1932, in the midst of one of the "Rek" areas. The preliminary surveys of Sind and Rajputana were attended to during 1932. From June 1933, closer attention was devoted to intensive surveys of particular areas with the aim of having continuous observations of the activities of the solitaria locusts during the different seasons of the year. From June 1934, intensive observations were started at certain outposts opened in parts of the Indian Desert areas and in parts of southern Baluchistan.

During the current year—1936—intensive survey work was in progress at Nokh, Sardarshahr and Chachro in the Desert areas, at Ambagh in the Lasbela State, and at Pasni, Gwadar, Turbat and Panjgur in the Mekran area.

The results obtained in the course of the work may be briefly summarised as follows.

1. The surveys have made it clear that the area of habitation of the solitary phase of the Locust (in other words, its permanent breeding grounds), extends over a very large area, made up of (1) partly the "rek" or sandy

coastal areas along the Arabian Sca and partly the interior of Mekran, and (2) the major part of the areas of the Great Indian Desert. On the whole, the region of 'habitat' of the Desert Locust is mainly of a sandy nature.

During the last 5 years, the locust has been found to be present in the above areas in greater or smaller numbers and to breed there regularly in the event of rainfall.

- 2. Breeding of the solitary locust would appear to be absolutely dependent on the fall of rain sufficient to wet the sandy soil at least to a depth of one foot. Wherever the sand has become consolidated into fairly firm soil, the soil moisture evaporates rather quickly, and locusts cannot lay eggs, after the lapse of about 3 to 4 weeks, in such soils; on the other hand, wherever the surface layers are of wind-blown sand, they tend to conserve the moisture in the deeper layers for a longer time. The length of the period of breeding would, thus, depend on the nature of the soil and on the occurrence of frequent showers.
- 3. The experience of the last five years has shown that good rainfall will lead to extensive breeding on 'rek' or desert areas and bring about a considerable increase in the locust population. The latter, however, has not so far brought about a concentration of numbers or led to the transformation of the phase solitaria into phase gregaria. On the other hand, such a concentration followed by transformation was noted to occur in 1935, in certain isolated sandy areas in the interior valleys of Mekran, large numbers of hoppers having been found in a crowded condition in small patches of cultivation, probably as a result of concentrated egg-laying by migrant locusts from the coastal areas. The hoppers may be taken to represent, in great part, the second generation of the season. Such spots may be deemed to function as "outbreak centres" and to serve as points of origination of the swarms. A study of the past records of the Mekran area has shown that such "outbreak" centres had come into existence in the past in parts of the Kulanch valley in 1926 and parts of the Dasht valley in 1923.

Since the areas of Iranian Mekran are more or less similar in general character to those of the adjacent province of British Mekran, it may be presumed that such 'outbreak centres' had also developed in the Iranian area at the time of the great locust incursion noted in 1935, and probably also during the year 1926.

Such 'outbreak centres' have not so far been met with in the Rajputana area, but perhaps they may be expected to occur there during years of extraordinary multiplication.

4. Occurrence of migration among the solitary locusts.—One of the items of study undertaken at the Locust Field Research Station at Pasni and elsewhere has been the determination of the relative density of locust population at different parts of the year. As a result of continuous observations made from 1932 to 1936, it has been found that the locust population at any particular place is subject to great fluctuation in the course of a year. Local breeding occurred whenever there was rainfall and led to a definite rise in the population. But in certain cases, it was observed that an increment in the numbers occurred in spite of the absence of breeding, and in such cases it was also

noted that there was a change in the biometrical characteristics as well as the general colouration of the locust population. At other times, a perceptible decrease in the numbers was noticeable, which could not be ascribed to the activities of natural enemics.

During the year 1935, however, at the time of the occurrence of an incursion of locusts of a considerable magnitude in various parts of N. W. India, definite evidence was obtained as to the capability of even the solitary (or rather the non-gregarious) locusts to migrate long distances by flight. In fact, they would appear to have migrated from Mekran into the Rajputana areas in summer and to have bred there during the monsoon rains, and the new generation produced in the desert areas would appear to have reached the coastal 'rck' areas of Mekran in October, November and December 1935. Observations continued during the current year have served to confirm the existence of migration as a general phenomenon, —from west to cast in early summer and east to west in autumn and early winter.

Various anomalies of distribution had been noted during the Locust surveys made during the years 1932 to 1934, which had been found difficult to account for at the time, but on the basis of the facts of migration among the solitaries that have since come to our knowledge, those data can now be easily explained.

Since the solitary locusts are now known to breed in the 'rek' areas during the spring and migrate to the desert breeding grounds for breeding during the summer rains, the 'rek' areas of Mekran and the areas of the Sind Rajputana Desert can no longer be considered to be distantly situated, separate breeding grounds, but rather to be complementary to one another.

In the course of a biometrical study of the collections of locusts made during the years 1931 to 1936, it has been noticed that there is a rough correspondence in the character of the locust population, as judged by the proportion of the different Elytron/Femur ratios and the relative dominance of 6 or 7 eye-stripes, between the forms found in winter or spring in Mekran and of those found in the preceding autumn in Sind-Rajputana, and between the forms produced in Mekran in spring and early summer and those found at the beginning of the monsoon in the Rajputana deserts.

5. In the course of the survey work, a good representative collection of the Acridida of the desert regions has been made, most of which has been identified by the Imperial Institute of Entomology, London. A collection of various birds, lizards and other animals affecting the life-economy of the locust has also been made and studied as far as possible.

An exhaustive collection of various plants found in the desert areas of Sind, Baluchistan and Rajputana has been made in the course of survey work, and has been examined and worked out by the Curator of the Herbarium, Royal Botanic Gardens, Sibpur. As far as possible, the local names under which each plant is known in different linguistic areas have been collected, and a list of the plants has been prepared for publication.

Wherever possible, observations have been made in regard to the plants preferred by locusts and hoppers of the solitary phase.

II.—Ecological Studies of the Solitary Phase.

- 1. Meteorological Observations.—The following observations have been under record at Pasni since 1932:—
 - (a) Stevenson Screen-

Atmospheric temperature—

Maximum and Minimum.

Relative Humidity-

Maximum and Minimum and at 8 A.M. and 5 P.M.

- (b) Black Bulb and Grass minimum temperature at 2" above soil surface from July 1936.
- (c) Open air temperature.
- (d) Bush temperature and Bush humidity (maximum and minimum)
- (e) Soil Temperature-
 - 1. Surface maximum and minimum.
 - 2. 2-inch depth maximum and minimum.
 - 3. 4-inch depth maximum and minimum.
- (f) Soil moisture: at 2-inch depth and at 4-inch depth once a weekand after rainfall.
- (g) Evaporation: Piche Evaporimeter: (a) in shade, (b) in sun.
- (h) Sun-shine Recorder: (since July 1936).
- (i) Wind: Direction: Velocity and mileage perday by Anemometer.
- (j) Barometric Pressure with an Aneroid Barometer.
- (k) Rainfall.
- (l) Depth of penetration of rain into sandy soil.
- (m) Occurrence of fogs and dews and their penetration into the sandy soil.
- (n) Clouds and other phenomena.

A thermo-hygrograph has recently been added to the equipment at Pasni.

Many of the above data have been under record at Ambagh since 1933, the observations being representative of 'reks' of the eastern type coming under the influence of summer or monsoon rainfall.

Since June 1934, simple observations of atmospheric temperature and humidity in screen, rainfall, etc., have been recorded at the Desert Outposts of Nokh, Sardarshahr and Chachro.

The various observations recorded have been found of great use in studying the response of the locust to changes in the climatic conditions in the different areas.

2. Field Observations.—During the periodical surveys made in the breeding grounds, locusts found in nature were kept under close observation to note how they were affected by changes in their general environment.

From observations made during the last 6 years (vide Table I), the factor that was found to have the greatest influence on their life-economy was rainfall. Breeding occurred only when there was rainfall sufficient to bring about a fairly deep penetration of moisture in sandy soils. In cases where locusts were already fairly mature at the time of the occurrence of rain, eggs were laid almost immediately, while in other cases sex-maturation was apparently hastened thereby.

As observed under semi-natural conditions, in the case of locusts in breeding cages kept in the open, the rate of development of the embryos and of the growth of the hoppers quickened with the rise of temperature. The shortest period of embryonal development as observed in cages under semi-natural conditions during the last four years at Pasni was 12½ days in mid-summer, and the longest was about 73 days during the winter period. The shortest duration of the hopper period recorded under such semi-natural conditions was 31 days during summer.

As to the number of generations passed through in a year, it was found that, under normal conditions, there was only one brood during the year on the Pasni 'Reks'. In a year of rather protracted and heavy rainfall, as in 1933, when there were two heavy falls, the first in February and the second in April, two generations were noted to follow each other rapidly. At Pasni, breeding occurs usually only during the rains of the winter period, but summer breeding may also occur whenever there is considerable summer precipitation, as had happened in 1930 and 1932. There was only summer breeding in 1932, while in 1930 there was, presumably, both spring and summer breeding.

In the Rajputana area, two successive generations have been noted during years of well-distributed monsoon rainfall, as had, for instance, happened recently in the Bikaner area (1936).

In order to determine the number of generations that the locust might pass through during a year on the 'rek' areas of Pasni, provided the locust were given the necessary conditions favourable for egg-laying and development such as moist soil and fresh food, successive broods were under observation, during the last 4 years, in cages kept under semi-natural conditions in the open, and it was found that four successive generations could be produced within a period of 13 to 14 months. That such continuous breeding can actually take place under natural conditions at Pasni has been demonstrated by the records of the occurrence of freshly hatched hoppers of the locust for over 9 months in the year, in certain special areas of the Pasni 'Reks', during years of plentiful rainfall as in 1933 and 1935.

During every period of breeding, field observations have been made in all the areas of occurrence, as to the earliest time of appearance of first stage hoppers and of freshly fledged adults, and also as to the latest time 'of persistence of hoppers.

3. Food Preference.—Observations made in the field have shown that the hoppers of the solitary phase have definite preferences for certain food-plants, though in the event of their non-availability they may take to other food-plants usually not much liked. On the Western 'Reks' of Mekran, Marrand

(Heliotropium undulatum) is the plant most preferred, but in its absence, 'Balibur' (Aerua javanioa), and 'Kulliohk' (Cyperus arenarius) are taken. In the Eastern 'Reks' in the Lasbela area, 'Marrand' is scarce, and the plant most preferred is 'Kharzan' (Scricostoma pauciflorum), and next in the order of preference were Aerua javanica and certain grasses. In the Sind-Rajputana area, the plants most liked were Indigofera cordifolia, Aerua javanica (locally known as 'Booh'), Tribulus terrestris, Cyperus sp.; young 'Bharut' grass (Cenchrus catharticus), and 'Vishani' (Tephrosia sp.).

Experiments on Food-preferences were carried out to a certain extent in 1932 at Pasni by Dr. K. R. Karandikar, and in 1936 by Dr. M. L. Roonwal at Pasni and Mr. D. R. Bhatia at Chachro. An account of these will be included in the Annual Report for 1936.

4. Effect of the quality of food on Sex-maturation.—Experiments have been in progress at Pasni since 1935, and at Ambagh since May 1936 to test the effect of food on the sex-maturation of the Locust. They have shown that fresh, succulent shoots of a food-plant have a definite stimulatory effect in hastening sex-maturity, as compared with the leaves of over-mature old branches, and also that certain plants, such as tender Jowar, and tender Maize, "Marrand' (Heliotropium undulatum), and 'Kullichk' (Cyperus arenarius) are able to bring about sex-maturity much earlier than others. At Ambagh, "Kharzan' (Scricostoma) and 'Booh' (Acrua) appeared to give much better results than at Pasni.

The results in regard to Jowar and Maize may perhaps be of particular significance, since almost all cases of incipient outbreaks (the outbreak centres') were associated with patches of cultivation, especially of Jowari.

- 5. Rhythm of Locust Activity.—A fair amount of attention was paid during 1933, 1934 and 1935 at Pasni in regard to observations on this subject. A note on the observations made so far was prepared by Dr. Roonwal and was included in the Annual Report for 1935.
- 6. In the course of the various experiments in progress at Pasni, records of the duration of the different stages at different seasons, the sex-ratios of the hatchings, the colour of the hatchings, the length of life of adults, the number of egg-masses laid by individual females, etc., were made. During 1936, a considerable amount of work was done on the development of the eye-stripes among the hoppers.

III.—BIONETRICAL STUDY OF COLLECTIONS OF LOCUSTS.

Collections of locusts made, since 1931, by the locust survey staff have been to a large extent examined, and notes have been taken for each individual locust examined in regard to (1) the Elytron/Femur ratio, (2) the number of eye-stripes, (3) the colour of the hind-wings, and (4) the general colouration.

1. The Biometrical Ratios.—In making a biometrical examination of specimens of Sohistocerca, reliance has been placed mostly on the Elytron/Femur ratio, as it appeared to be most expressive of the phase characteristics of the Desert Locust. The other ratios employed in the case of Locusta migratoria, while useful in cases where femora have been lost, are not so expressive and are

rather difficult to work out accurately. Typical forms of 'gregaria' collected from swarms found in 1931 have shown E/F ratios ranging from 2·18 to 2·30. while typical 'solitaria' specimens developing from green hoppers on wild vegetation have shown ratios between 1·92 and 2·00. Ratios of an intermediate character have often been met with among locusts of non-gregarious character found in the desert, and since the transition from typical gregaria to typical solitaria is quite gradual and complete, an arbitrary limit has been, for the sake of convenience, placed at 2·05 for solitaria and at 2·16 for gregaria, to mark off the intermediate or transiens ratios, which would thus fall between 2·06 and 2·15 (both inclusive).

2. The Eye-stripes.—The discovery made by Mr. M. L. Roonwal in January 1936, of the existence of two types of eye-stripes in the Desert Locust has proved to be a very significant character in the study of locust populations. Specimens collected from swarms have invariably been found to be possessed of 6 stripes, while typical extreme 'solitaria' bred in the deserts—especially the female ones, have mostly 7 stripes. The forms collected at the time of the great incursion of 1935 were found to have mostly six stripes, and the same was the case with the pink and yellow forms that migrated into the Pasni 'reks' in May 1932.

A study of the populations found at different parts of the year has shown that, as a rule more of the 6-striped forms are produced in spring and summer in Mekran, while more of the 7-striped ones are generated in the Sind-Rajputana deserts during the progress of the monsoon.

While the exact significance of the number of stripes is not yet clear, the available evidence may perhaps lead one to associate the number of the stripes with the number of moults passed through in the hopper stage.

- 3. Colour of the Hind-wings. -- The colour of the hind-wings has been found to be of much help in determining the approximate age and state of development of the locust. Hyaline wings are characteristic of a recently fledged generation. A light yellow tinge is assumed in about a fortnight under normal conditions, and is generally expressive of the onset of adolescence, while a deep yellow would usually denote a state of full maturity. In certain cases, the whole of the hind-wing assumes a light pink colour, while in other cases, the colouration is restricted to a distinct patch of light or deep mauve, blue or pink at the base of the wings. This has been found to be characteristic of forms undertaking long migrations in sunny weather. The development of the pink, blue or mauve colour would appear to be due to the prolonged exposure of the hind-wings to the rays of the sun during active flight, and this assumption has been to a great extent confirmed by the results of certain experiments, wherein one of, the elytra of locusts kept in cages in the open was cut away so as to keep the hind-wings of that side exposed to the sun's rays. In the case of many of these, pink, mauve or blue was found to appear in varying degrees of intensity on the exposed hind-wing.
- 4. The Body Colouration.—General observation has shown that, unless locusts happen to be in a state of migration, they tend as a rule to assimilate the general colouration of their surroundings. Forms found in the desert usually assume bright stripes, which serve to break the monotony of the ground-colour M253ICAR

of their body and assimilate it to the light and shade of the stems of grasses or other plants found on the soil. A good many of the solitary locusts found among thick green vegetation in Rapputana and Lasbela in July-August were found to have developed patches of fairly bright green on their body and elytra. At a later stage, when grasses had dried up, the prevalent general colouration of locusts was a hay-brown. Specimens found on stony soil were generally noted to possess a dark brown colour.

When the examination of all the available collection of locusts of past years is completed, it is anticipated that a study of the results would yield valuable information in regard to the details of locust developments in the near past.

IV .- STUDY OF OLD RECORDS.

During the last six years, all available records relating to locust activities in the past within the areas of Sind, Baluchistan, Rajputana and Bombay have been examined and extracts taken for study. As far as possible, rainfall data for various areas of N. W. India affected by locusts have also been collected for the past years.

The information thus accumulated has been studied as far as possible and the results may be considered under the following heads:—

- (1) Locust activities within the Indian area during the last cycle of 1926-1931, (2) Correlations of Meteorological data with recorded locust movements during 1926-1931, and (3) Locust developments of years prior to 1926.
- (I) The Great Cycle of 1926-1931.—All available information relating to this cycle for the areas of Sind, Rajputana, Baluchistan and Western India States has been classified chronologically and the data concerning the movements and activities of locust swarms have been mapped month by month, and as far as possible correlated with available meteorological data for these years. Data in regard to the other areas of North-West India, viz., Punjab, North-West Frontier, United Provinces and Central India have been studied by Khan Bahadur Afzal Hussain, I. A. S., formerly Locust Research Entomologist to the Imperial Council (1930—1933).

From the information gathered in regard to the areas of Sind, Baluchistan, Rajputana and Western India States, the following inferences may be made.

1. One of the centres from which the last great infestation of 1926-1931 originated would appear to have been the province of Mekran, the main factor that led to its development having been the heavy and widespread rainfall of January 1926 inducing extensive breeding of locusts on the coastal "rek" breeding grounds and leading to their subsequent concentration in certain 'outbreak' areas in the interior of Mekran, such as Kulanch. The subject has been dealt with in some detail in a paper published in the Indian Jl. of Agricultural Science, III—part 5, October 1933—"Mekran—Possibly the Country of Origin of the Great Locust Invasion of Sind in 1926".

- 2. The initial concentrations produced in June from the 'outbreak centres' in Kulanch—and probably also from similar sources further west in Iranian Mekran—had presumably migrated during June, July and August probably partly as small swarms and partly as individual locusts as had happened in 1935, into Sind and Rajputana deserts. The very favourable rainfall of 1926 monsoon had evidently served to induce rapid breeding and to bring about the formation of the huge swarms, which spread south, west and north in the autumn of 1926.
- 3. The western swarms probably penetrated far into Persia and formed the main source of the infestation recorded in the spring months in the Persian area in 1927.
- 4. During December 1926 and January 1927, swarms did not show much activity and probably over-wintered wherever they were overtaken by cold weather. Within Indian limits, the following areas, viz., the greater part of southern Baluchistan, parts of Sind, and south Punjab and the plain of Kachhi, evidently functioned as over-wintering areas. In February 1927, the swarms became active again and laid eggs wherever rain had fallen. There was considerable egg-laying in Mekran, and from March onwards the swarms began to move gradually north and north-east into the uplands of Baluchistan, ultimately reaching the farthest and highest valleys, such as those of Quetta-Pishin and Toba Achakzai, in May. Considerable egg-laying occurred in these regions.
- 5. Locusts of the new generation were ready to fly by May in the lower valleys and about a month later in the upland areas. The swarms gradually moved eastwards into Sind, Punjab and Rajputana by June-July. Breeding commenced in August after the fall of the monsoon rains in the desert areas of Thar-Parkar and Rajputana.
- 6. The adults of the new generation were ready to assume flight at the end of September and during October, and moved in general in a western direction into Baluchistan during November and December 1927.
- 7. Over-wintering occurred in parts of Sind and southern Baluchistan, as in 1926.
- 8. During the years 1928, 1920, 1930 and 1931, the activities of the swarms more or less resembled those of the year 1927. During the months—February to June, the swarms bred in the winter rainfall areas in Baluchistan, the volume of the breeding and the localities affected, in particular years, being determined by the amount and the distribution of rainfall in the different areas. During the months of May, June and July, a migration of the new generation of locusts took place from the places of breeding into Sind, Punjab and Rajputana. During the monsoon months, summer breeding occurred in these areas wherever good rainfall was recorded, and the swarms that resulted therefrom flew either castwards into Central India, or southwards into the Kathiawar States, or westwards into Baluchistan.
- 9. Since the flights to the east or to the south do not lead the locusts into regions where further breeding is possible these are of little consequence. It is the west-bound flight, that take them to regions where further multiplication

can take place and thus help the infestation to continue from one year to another. The records show that westward movements did occur during the years 1926, 1927, 1929 and 1931, and that the west-bound flights were particularly strong in 1929, while in regard to the years 1928 and 1930, there have been no indications of westward movements.

- 10. The continuance of a locust infestation, once it starts, would appear to be dependent on the ability of the locust swarms to transfer themselves from areas of winter rainfall to those of summer rains, and vice versa, at the right time, so as to be able to pass through two generations during the year, and its decline is probably to be attributed to the failure of rains in one or other of the breeding areas and the consequent failure of breeding.
- 11. The decline of the last locust cycle is probably due to a combination of several unfavourable factors. In spite of heavy multiplication in the summer of 1930, there was an absence of west-bound flights in the autumn of 1930, so that the swarms found in Baluchistan in the spring of 1931 were of comparatively small dimensions, and the spring breeding of 1931 was, therefore, somewhat limited. Though the resulting pink swarms migrated into Sind, Punjab and Rajputana, in June-July, there was no breeding in Sind and Lasbela, and except in the Rajputana area where heavy rainfall was followed by considerable breeding, there was little multiplication even in Punjab and United Provinces. Westward flights occurred in the autumn of 1931, but owing to a total failure of winter and spring rains in 1932 in Baluchistan, locusts could not breed, with the result that the infestation practically came to an end.
- (II) Correlation of Meteorological Data.—Some attention was paid during 1935 and 1936 to the correlation of meteorological factors with the recorded data of locust activities during the last great locust cycle.

First among the problems relating to locust movements is the determination of the factors that impel large bodies of locusts bred in a particular rain-belt to fly large distances to reach a different region of rainfall for purposes of breeding. Apparently it would seem as if the swarms were migrating from a zone of low humidity in order to reach another of high moisture content, but it is somewhat difficult to imagine how locusts could orient their flights to reach a region of higher humidity situated hundreds of miles away.

While examining the various daily meteorological data recorded in the Indian Daily Weather Reports for different years relating to the areas of summer and winter rainfall where locusts usually breed, it was noticed that, at the close of the seasonal rains, there is often a sudden rise in temperature and a simultaneous fall in atmospheric humidity, generally accompanied by a change in the seasonal direction of the winds. Some of these areas usually develop into zones of high saturation deficiency, in which owing to the high soil surface temperatures and the low humidity, locusts apparently find it difficult to live. Such dry hot areas are found developing in low basins, such as those of Kharan and Chagai in western Baluchistan and those of Bampur and Seistan in Iran, from May onwards. Dry scorehing winds generally from a north-west direction are, moreover, prevalent in these areas for nearly four months in the year. Along the constal areas of Mekran and Sind, on the

contrary, the cool south-west breeze establishes itself from April onwards, and in May-June it strengthens in velocity and duration and penetrates far inland in eastern Baluchistan and north-west India. In their efforts to flee from the interior areas of intense aridity, the flying locusts, sooner or later, reach the S. W. current and would appear to be carried by stages into the interior of north-west India. The progress of their flights apparently comes to an end only when they come into contact with the conditions of high atmospheric and soil humidity brought about by the fall of monsoon rainfall.

Similarly, in the Rajputana desert areas, soon after the south-west monsoon withdraws about the end of September or in October a period of bright and cloudless days follows, bringing about a sudden rise in temperature and a fall of humidity, and causing the development of a zone of high saturation deficiency. Locusts would appear to take advantage of the prevailing winds at the time and flee from such conditions. If the south-west winds still persist, the locusts would be carried towards the east or the north-east, and if north-west winds prevail, they would reach Kathiawar, and if north-east winds, which normally characterise the autumn period in the desert area, develop, a westward movement would ensue. The development of west-bound flights or their absence in particular years would, thus, appear to depend on whether the usual change in the direction of winds from the south-west to the north-east sets in early or late in the autumn.

Secondly, a great deal of attention was paid during 1936 to the study of the correlations of the directions of recorded locust movements and the winddirections noted in the Indian Daily Weather Reports. This work was, however, much handicapped by the fact that in a good many cases the time of occurrence of the flights is not known, while the wind-directions shown in the Weather Reports are referable to observations made at 8 A. M. As is wellknown, the winds noted in the afternoons may often be totally different in direction from those noted in the mornings. Again, in many instances, there are no records of wind data for the places where locust flights had actually occurred, and the probable directions can be inferred only by studying the data for the nearest recording stations. Even making allowance for all these various handicaps, it has been generally found that the flight-directions are remarkably coincident with the wind-directions. Such a coincidence was specially noticeable in the case of certain flights recorded in June-July 1930 in the United Provinces. During May and the first half of June 1930, the movements were from west to east in accordance with the prevailing wind directions at the time and the swarms had by June actually penetrated into Bihar, but by the second fortnight of June, with the development of the monsoon current from the Bay of Bengal, the direction of flights was reversed and the eastern half of the United Provinces was clear of locusts by the end of July.

Thirdly, in general, the occurrence of heavy oviposition was almost always to be found to be correlated with heavy rainfall and an absence of breeding with the failure of seasonal rains.

(III) Locust Invasions prior to 1926.—A vast mass of data has been gathered from all available sources, mainly season reports published in the Gazettes of various provinces and various Diaries and periodical reports. The

data have been classified chronologically after extraction, and have been cursorily studied. They await detailed examination and mapping, and correlation with meteorological data.

Of the above, the data extracted from the Sind Official Gazette in regard to locust occurrence in Sind from 1872 onwards have aheady been carefully examined and correlated as far as possible with the available data for Sind, Rajputana and Baluchistan. A graph has been prepared, from which it would be seen that there have been in Sind, during the last 66 years, i.e., from 1869 to the present time, 4 main cycles of locust infestation lasting 6 to 18 years, with intervals lasting 4 to 7 years, and also that every year there had been flights of swarms from Baluchistan into Sind during May, June and July, while during the autumn the movements were in the reverse direction, i.e., from the desert areas in the east to the Baluchistan area to the west of Sind. With the valuable information collected in regard to the activities of locust: during the current non-locust period, it should be possible to reconstruct the past history of the previous invasions to a great extent.

Data available for the Punjab from 1869 to 1925 (kindly supplied by the Punjab Government Entomologis), and for Bombay from 1869 to 1931, and for Rajputana and Baluchistan from 1890 onwards, have been cursorily examined, but await a detailed study.

From the data extracted for Bombay, information regarding the past activities of the Bombay Locust (*Patanga succircta*) from 1870 to 1926 has become available for detailed study.

V.—Some Practical Issues of the Present Work.

In regard to the practical issues arising from the research work now in progress, the following statements may be made.

- 1. With the present fuller knowledge of locust migrations, and the migration routes, it would be possible, in the event of another infestation developing, to prognosticate with a fair degree of accuracy where attacks of swarms might be expected, so as to enable the provinces concerned to be prepared for the invasion beforehand.
- 2. Since swarms developed in Iran, and possibly even in Central Asia, may be expected utlimately to reach India during summer, and since also those bred in Sind and Rajputana deserts can reach southern Iran during the autumn and winter months, the need of international co-operation for fighting the pest cannot be emphasized too strongly.
- 3. In regard to the primary breeding grounds and the 'outbreak centres', there is little doubt that a great many of them do occur within Iranian limits just as they occur in the Indian area. Since the solitary locusts also have been found to be able to migrate long distances, it is evident that there is an intimate connection between the India Desert areas and the coastal 'reks' of British Mekran and Southern Iran. If, with the object of arresting the initial infestations and thus of nipping the evil in the bud, it is proposed to tackle the 'outbreak centres', as they develop, the experience of 1935 would show that, for a successful achievement of that end, an intimate co-operation of effort is indispensable between India and Iran.

T. RAMCHANDRA RAO, Locust Research Entomologist, Karachi.

	:	:	9	12	19 -0	28	:	Nit	Population low.

Remarks.	Four locusts observed during one survey only (Gurani). On all the other surveys no locusts were found. Population low.	Population low.	A sudden increase in population was noticed on 8th October and 1s attributed to an immigration, probably from Kolwa where rainfull had been received in September. The locusts observed belonged to a recent generation.	In the third week of October, population was almost nil. On 20th October several locusts were noticed in the vicinity of Pasni Town and on the survey done on 30th October, the locust population worked out at 274 per square mile. The locusts belonged to a recent generation and were probably migrants from the summer breeding areas. N. B. Winds prevalent.	The immigration of clear-winged locusts continued during this period. Red mites were present on wings of many locusts.	До.

STATEMENT D.

Details of Morements of the Locust Research Entomologist during 1936.

Serial No.	Month.	Duration of Visit.	Particulars and purpose.
1	January	14th to 25th January	To attend the Meeting of the Locust Committee at New Delhi on 20th
2	February-Match	16th February to 19th March.	and 21st January. Periodical visit to Pasni; and a tour in the interior of Mekran to examine the areas of incipient swarming (23rd February to 4th March).
3	April	30th April	Periodical inspection visit to Ambagh.
4	May-June	24th May to 6th June	Periodical inspection visit to Pasni.
5	June	16th Juno	Inspection visit to Ambagh.
6	June-July	21th June to 4th July	Inspection virit to Chachro Outpost and a tour in the Thar area in Mithi
7	July-August	22nd July to 4th August	Tq. Inspection of the office of the Assistant at Barmer and of Nokh and Sudarshahr Outposts and a tour in the interior areas of Jaisalmer and Bil aner States.
8	August	9th to 16th August	Inspection of Pasni Station.
9	September	11th to 21st September	Inspection of Sardarshahr Outpost and a tour of survey in the interior of the Bikaner area to note the effect of the recent heavy rains on Locust breeding.
10	October	4th to 20th October	Periodical inspection of Pasai Station. Exemination of the results of pre-
33	November	7th November	Periodical veit to Ambagh Station.
12	December	2nd December	Visit to Ambagh Locust Research station to show the work in progress and about the nature of the latited breeding grounds to Sir John Russell. O B.E., F.R.S., Expert Schuttlie Advicer to the Imperial Council of Agricultural Research.

STATEMENT L-I.

Effect of Exposure to Sunlight on the Colouration of Hind-wings of Schistocerca.

Particulars of Experiment.	Dates of starting.	Drtes of Examination L.	Dates of Examination. II.	Remarks
Paul.	8th Jine 1936	21th June 1036	6th July 1836	Days very bright and sunny during June, July was maify and cloudy
I) Regal elytron removed: Number of locusts in enge kept in sunshino. Siz (2 males and I females).	The hndwings including the wing-bases by aline.	I. Hind-wings have ussumed a hight vellow tunge. (I male missing) wing-bree park or mavro in all on the right sude; two specimens	1. Wings light yellow, wing- bries pink or mauve on both sides, but colour deeper on tho right side.	The general body colour of the locust was panking the 8th June, gradually the colouration assumed a darksh blue bue.
(2) Both elytra removed: Number of locusts kept in cage in the sun: Eight (£males and 4 females).	Ditto	2. Wings light yellow in all; wing- bases pink or maye on both sides except in one specimen.	2. Both sides pink, or mrave, except in one.	In July, the hud-wags assumed a deep yellow colour the purk and mauve being lost.
Experiment II	4th November 1936	20th November 1036	6th December 1936	Days mostly sunny and bught except in the mornings.
10 locusta (4 males and 6 females).	Hind-wings hyuline mostly but light yellow in some	 Wings tight yellow; light pink or marve in 3 specimens, on right side in one, and on both sides in two 	I. Wings hight yellow to yellow. Wing-birses light or deep mature in most; in one puck turning into matuse; both sides affected	

				There were a few sunny days in June, but by the let week of the month, the weather ohanged with the break of the mansoon.		Days mostly sunny and bright.	Days runny and bught mortly.	
	2. Wings yellow in most: hises: manve or pink in all and on both sides.	3. Wings yellow to light yel- low; buses: light tinge of mante on both wings in 3 locusts.		:	16th /21st Oatober 1936.	Nauve tings found also on left wing at the base.		
	2. Wings light yellow in most; wirgs hases, pink or maine on both sides in 3 miles.	3. Wings light vellos in most; wing tyres light miture in hoth wings of 2 frances.		Examined in July, it was found that there was no descripment of blue or manre at the wing-have, the whole wing having turned jellow.	7th Repromber 1936	Mouve or blue tinge distinct at the base of the right hind-wing	22-27th November 1936	Tink n suse or blue tings was found to have appeared at the base of the right wing
•	;	•	:	;	:	•	:	*
	Ditto	Dutto	17th June 1936	Wings fully byvline	16th September 1936	Wings folly hyakne	24-28th October 1936	Wings fally byaline
(2) Bol's clytra removed:	10 locusts (4 males and 6 femiles).	(3) Both elytra inlact:— 10 locusts (3 maler and 7 females). (Control).	ANBAGIL. Experiment !— Bight elytron remot ed:	4 locusts, fledged on 17th Juno 1936, were used. Cage Lept in the sun.	Experiment II— Right elytron removed:	5 locusts which became schills on 16th September 1936 were used in the experiment.	Expernment III— Right clytran remacal :	Six specimens which became adults between the 24th and the 28th October were used.

STATEMENT L-I-contd.

Particulars of Experiment.	Dakes of starting.	Dates of Examination L	Dates of Examination II.	Remarks.
Kabachi. Seperantal (—	16th June 1936	10th July 1036		
A dozen specimens with hya- line wings were selected from locusts that had recently become actilitie in enges, and had the elytter removed, and kept in the sun enclosed in a wire-gauze onge.	Wings fully transparent	Wings had assumed a light yellow to deep yellow colour. There was no lings of bias or mairs at the base of the wings.	:	Days were amny during the middle of June, but by the last week, it became cloudy, and several showers were also recorded early in July.
apenment II	10th September 1936.	22nd October 1936		
60 recently fledged specimens had their right elytra removed, before being enclosed in a cage.	Wings fully bysline	About 20 loousts had definitely developed a rank or matter targe at the base of the right wings while the left wings were mostly hyntane.	:	Days in September October were mostly bright, hus as the cages were kept in a place surrounded by tall buildings they did not get more than an bours of sun-shine on the whole.
rperiment III—	22nd October 1036	14th December 1036		
The experiment was repeated in October with 40 newly fledged specimens.	Wings byaline	A purt or mauve tinge was notio- ed only in 12 specimens.	:	Days during November-De- cember movily bright, but the general temperature lower than in October.

STATEMENT L-II.

Showing the effect of Sunlight on "Gregarious" Adult Eyes.

	Cage No., num	ber of locusts, and condition	of eyes,
Date.	SR ₃ (Sunshine) 2 females 4 males.	SR. (Sunshine) Ē fomales 3 males.	S ₁ (control) (Shado) 2 females 3 males.
26th May 1936	Eyes claret coloured. No stripo visible, except one at anterior end of eye	Eyes as in SR ₁	Eyes uniformly claret coloured. No tripes visible.
lst Juno 1936 .,	In three locusts the stripes have cleared; in the other three, not visible.	In four-locusts the stripes have cleared: in the other four, not visible.	Eyes as before. One main died.
28th June 1936	Four locusts with clear stripes; the other two without stripes. (One male and one female died).	All locusts with clear stripes (Two males and two females died)	Eyes as before, except in one female where the two anterior stripes are faint- ly seen.
28th July 1036	Stripes clear in all (One male died) [Locusts transferred to smaller cage (1'x1'x1's) but still Lopt in the sun].	Stripes clear in all Lo- custs transferred to amaller cage (1'×1'×14'), kept in shade.	Ditto.
7th August 1936	Only one female left, the rest having died. Eye stripes dui l.	Only one male left, the rest having died. Eye atripes dull.	Ditto.

STATEMENT M.

Results of Experiments with the Reliberation of Collected Locusts after marking.

			*		
Months.		Numbor liberated.	Number recovered and date of recovery.	Partualiers of recovery.	Interval between liberation and recovery.
			Равчт, 1935.		
December 1934	:	About 5 liberated on 29th December	1 on 23rd January 1936	Near place of liberation	25 days.
February 1935	;	15 locusts liberated botween 25th Web- ruary and 3rd March marked with white paint on therex.	One male with white print found on 6th March.	Near place of liberation	About 10 days.
April1935	:	160 specimens marked with green paint and liberated.	I specimen with green print on 22ml April, I on 27th April, I on 6th May, I on 8th May, and I on 10th May.	Within a mile of place of liberation.	Within 2 to 4 weeks.
Kay 1935	;	About 30 spoemens of locusts during first fortught, marked with red paint on wings and thorax.	I on 17th May 1936 at Rumra about 20 miles to the NE. of Pasni by the Ormara Lieldman.	About 20 miles	Probubly about a week.
			1 locust on 20th May on Adasti rek	About a mile	1 to 2 weeks (?).

STATEMENT O.

Painted-Box Experiments. (Dr. M. L. Roonwal).

In order to study the effect of the colour of environment on that of locusts, hoppers were reared in small, wooden boxes (9.5 cm. ×8.5 cm. ×12 cm.), with their inner walls painted in different colours. The boxes were closed on all sides except at the top which was of wire-gauze. The boxes were kept in the shade of the verandah and not exposed to direct sunlight. To start with, green hoppers were taken in nearly all cases, except one, when a black hopper was used. Table 10 gives the eight colours used and the results obtained therefrom:—

Table 10.

		Colour of the result	ing insect.
Inside colour of box.	rearing	Old hopper stages.	Adult.
Lemon yellow	• 1	Bright yellowish green	Light green.
Prussian blue	••	I awn or green base with black markings.	Brown sh or pinkish grey.
Mahogany	••	До	••••
Black	••	Dark green or dirty fawn bosswith bines markings.	Smoky brown or ash coloured.
Dark green	••	Bright green	Light ga en.
Signal red	••	Thrty green or orange	Grey with violet tinge, especially on hind legs.
White	••	Generally greenish white	Whitish fawn.
Light ochro (unusin wood).	ited	Pale green with or without yellowish tange.	Dull brown.

Out of nearly 64 experiments which were performed, only 19 reached sufficiently advanced stage to permit of any deductions being made. The rest

STATEMENT O-contd.

terminated with the death of the first or second hopper stages. The following is a brief account of each set of experiments:—

- 1. Lemon yellow.—Nine experiments were started for this colour, but five died in the first stage and two in the second. Of the remaining two, one was reared up to the fourth and the other to the adult stage.
- 2. Prussian blue.—Nine experiments were started for this colour, but six died in the first stage and one the second. The remaining two were reared up to the adult stage.
- 3. Mahogany.—Nine experiments were started for this colour, but five died in the first stage and two in the second. Of the remaining two, one was reared up to the third and the other to the adult stage.
- 4. Black.—Seven experiments were started for this colour, but four died in the first stage. Of the remaining three, two were reared up to the adult stage and one up to the fourth.
- 5. Dark Green.—Eight experiments were started for this colour, but five died in the first stage and one in the second. Of the remaining two one was reared up to the third and the other to the adult stage.
- 6. Signal red.—Nine experiments were started for this colour, but seven died in the first stage. The remaining two were reared up to the adult stage.
- 7. White.—Ten experiments were started for this colour, but six died in the first stage. Of the remaining four, two were reared up to the fourth, one to the fifth and one to the adult stage.
- 8. Light ochic (unpainted).—Three experiments were started for this colour. Of these one died in the first stage, the second was reared up to the fourth and the third to the adult stage.

Results. -It will be seen from Table 10 that some colours were apparently simulated, whereas in others the results were indefinite. Colours which were simulated to a greater or less extent were: light yellow black, dark green and white. Hoppers reared in the mahogany coloured boxes became fawn coloured in the fourth stage. This is not regarded as due to the mahogany box, since a hopper reared in the prussian blue box also became fawn. Moreover, the fawn colour sporadically appears in solitary hoppers reared in identically coloured cages, where the factor of the environmental colour cannot be correlated with the colour of the hopper.

It should be pointed out that one may not reasonably expect a locust to simulate any colour to which it is exposed, and that there are probably limitations to which the insect is subject in this respect. Nevertheless, the fact remains that, to a greater or less extent, the locust can simulate certain environmental colours. The results presented here broadly confirm those obtained on Locustana pardalina by Faure (1932) in South Africa, although the simulated colours are not precisely the same in both the cases.

STATEMENT P (I).

The development of Eye-stripes in individual Hoppers with 6 & 7 striped eyes (as determined by Dr. M. L. Roonwal).

			81,537	74,287	7,250			

N.B.—1. The increase of expenditure on account of Travelling Allowance of establishment under 'C—Pasni, etc.', is mostly due to the grant of leave to some of the superior staff who were paid Travelling Allowance under F. R. 105 (d) freed with S. R. 144 and to the transfer of Biometrical Assistant from Pasni to Karnehi in January and etce teres in May 1036, as Looust Research Assistant at Pasni. It also includes Travelling Allowance of Establishment for the month of January to March 1936 which could not be paid before the close of the financial year 1935-36.

Y. RANCHANDRA RAO,

The 22nd December 1936.

Locust Research Entomologist to the Imperial Council of Agricultural Research,

Karachi,

^{2.} The increase of expenditure under 'C—Passi, etc.—Contingencies etc.' is due to the purchise of new Scientific apparatus such as self-registering Thermohygrograph, self-registering Hygrographs and prement for the Tield eager provided last year at Passi and Ambagh, and was unavoidable. The purchase of Hygrographs was recommended by the Locust Committee in January 1930

^{3.} A sum of Ra. 6,000 was provided in the Budget for the year 1934-35 for Construction of Laboratory and residential quarters at Paral out of which Rs. 3,581 was spent in the year 1935-36 and the remainder Ra. 2,438 was paid during the current innancial year. The Building Supervisor who inspected the buildings after their completion in January 1935, has suggested ortain improvements to make buildings more stable. Provision has been made for carrying out the repairs which would cost about Rs. 902, for which sanction has already been granted by the Vice Chairman, I. C. A. R.
